

Extraction of Single and Double Differential Cross-Sections on Argon for CC1 μ 2p0 π Event Topologies in the SBND

Emilio Peláez Cisneros

September 18, 2024

Abstract

The precise measurement of cross-sections for a variety of interactions is critical to the success of upcoming flagship neutrino experiments. Of special interest are neutrino interactions that leave the nucleus in a 2-particle 2-hole state (2p2h). This note will present cross-section measurements for the production of 2p2h states on Argon. Using SBND data collected from the **period** of operation, we select events corresponding to a charged-current ν_μ interaction that left the Argon nucleus in a 2p2h state. These interactions produce a topology with one muon and two protons in the final state (CC1 μ 2p0 π). This analysis targets both single differential and double differential cross-section measurements for CC1 μ 2p0 π event topologies in a variety of kinematic variables. Comparisons are made to a set of theoretical models that explore different cross-section modeling configurations. Code for this analysis is available on [GitHub](#).

1 Introduction and motivation

2 Since many current and next generation neutrino oscillation experiments will utilize dense nuclear targets,
3 such as liquid argon (LAr), it is critical to characterize the impact of nuclear effects on neutrino cross-sections.
4 One area of interest are neutrino events that eject 2 nucleons from the nucleus, leaving it with 2 holes: known
5 as 2-particle 2-hole states (2p2h). The general picture is that the neutrino has a charged-current interaction
6 with a neutron in the nucleus, producing a proton with significant momentum; this proton interacts with
7 another proton, producing the 2p2h state. While the majority of 2p2h states are caused by Meson Exchange
8 Currents (MEC) [15], some nuclear effects, such as Short-Range Nucleon-Nucleon correlations (SRC) [10],
9 can also produce these states. In an accelerator-based liquid argon time projection chamber (LArTPC)
10 experiment, such as SBND, a charged-current (CC) muon neutrino (ν_μ) interaction that results in a 2p2h
11 state would have a final state topology of 1 muon, 2 protons, and no charged or neutral pions. While
12 there are existing measurements of CC1 μ 2p0 π events on argon, the analyses were statistically limited and
13 no cross-sections were extracted [1, 19]. There was a previous report with single differential cross-section
14 measurements from the MicroBooNE detector [20], but this document presents the first double differential
15 cross-section measurements of CC1 μ 2p0 π topologies on argon, using data collected from the period of SBND
16 operations.

17 2 Generator analysis

18 2.1 Signal definition

19 We choose charged-current muon neutrino interactions that result in one muon, two protons, no charged pions
20 with $P_\pi > 70$ MeV/c, no neutral pions or heavier mesons, and any number of neutrons. These interactions
21 are denoted as CC1 μ 2p0 π . We require the momentum of the muon and protons to be in the following ranges
22 (in MeV/c):

$$100 < P_P < 1200 \quad 300 < P_\mu < 1000 \quad (1)$$

23 2.2 Generators

24 The following generators are used to create events, which are then discriminated using the signal definition
25 above: NuWro, GiBUU, NEUT, GENIE G18, GENIE AR23. Information about these generators is
26 summarized in Table 1.

Name	Generator/Configuration
G18	GENIE v3.0.6 G18_10a_02_11a
AR23	G18 with SuSAv2 MEC model
NuWro	NuWro 19.02.1
NEUT	NEUT v5.4.0
GiBUU	GiBUU 2021

Table 1: Generator and configuration data.

27 The GENIE configurations we used are:

- 28 (i) GENIE G18 [2, 3]: This modern model configuration uses the local Fermi gas (LFG) model [9],
29 the Nieves CCQE scattering prescription [23], which includes Coulomb corrections for the outgoing
30 muon [11], and random phase approximation (RPA) corrections [22]. Additionally, it uses the
31 Nieves MEC model [25], the KuzminLyubushkin-Naumov Berger-Sehgal RES [6, 28, 16], Berger-Sehgal
32 COH [7] and Bodek-Yang DIS [29] scattering models with the PYTHIA [26] hadronization part, and
33 the hA2018 FSI model [4].
- 34 (ii) GENIE AR23: Same as the G18 model configuration but using the SuSAv2 MEC model.

35 The alternative event generators are:

- 36 (i) NuWro [12]: Includes the LFG model [9], the Llewellyn Smith model for QE events [18], the Nieves
37 model for MEC events [24], the AdlerRarita-Schwinger formalism to calculate the Δ resonance explicitly [13],
38 the Berger-Sehgal (BS) COH [7] scattering model, an intranuclear cascade model for FSI [24],
39 and a coupling to PYTHIA [26] for hadronization.
- 40 (ii) NEUT [14]: Corresponds to the combination of the LFG model [8, 9], the Nieves CCQE scattering
41 prescription [23], the Nieves MEC model using a lookup table [25], the Berger Sehgal RES [6, 13, 5]
42 and BS COH [7] scattering models, FSI with medium corrections for pions [2, 3], and PYTHIA [26]
43 purposes.
- 44 (iii) GiBUU [21]: Uses similar models to GENIE, but they are implemented in a coherent way by solving
45 the Boltzmann-Uehling-Uhlenbeck transport equation [21]. The modeling includes the LFG model [9],
46 a standard CCQE expression [17], an empirical MEC model, and a dedicated spin dependent resonance
47 amplitude calculation following the MAID analysis [21]. The DIS model is from PYTHIA [26]. GiBUU's
48 FSI treatment propagates the hadrons through the residual nucleus in a nuclear potential consistent
49 with the initial state.

50 2.3 Variables definition

51 Given the momentum vectors for the leading proton \vec{p}_L , recoil proton \vec{p}_R , and muon \vec{p}_μ , we define several
52 variables. First, we define the momenta and opening angle of each variable, denoted as $|\vec{p}|$ and $\cos(\theta_{\vec{p}})$, with
53 the appropriate index for each momentum vector. These variables are plotted in Figure 1.

54 We also define variables relating the multiple momentum vectors. First, the opening angle between the
55 protons in the lab frame, given by

$$\cos(\theta_{\vec{p}_L, \vec{p}_R}) = \frac{\vec{p}_L \cdot \vec{p}_R}{|\vec{p}_L| |\vec{p}_R|}. \quad (2)$$

56 Then, the opening angle between the total proton momentum ($\vec{p}_{\text{sum}} = \vec{p}_L + \vec{p}_R$) and the muon, given by

$$\cos(\theta_{\vec{p}_\mu, \vec{p}_{\text{sum}}}) = \frac{\vec{p}_\mu \cdot \vec{p}_{\text{sum}}}{|\vec{p}_\mu| |\vec{p}_{\text{sum}}|}. \quad (3)$$

57 The momentum transverse to the direction of the neutrino beam, which we denote $\delta\vec{P}_T$ and is given by

$$\delta\vec{P}_T = \vec{p}_T^\mu + \vec{p}_T^L + \vec{p}_T^R. \quad (4)$$

58 For the transverse momentum, we will be interested in its magnitude $|\delta\vec{P}_T|$. Finally, the angular orientation
59 of the transverse momentum with respect to the transverse muon is defined as

$$\delta\alpha_T = \cos^{-1} \left(\frac{-\vec{p}_T^\mu \cdot \delta\vec{P}_T}{|\vec{p}_T^\mu| |\delta\vec{P}_T|} \right). \quad (5)$$

60 We plot the differential cross sections of these variables for the given generators in Figure 2. We can also
61 see the cross section by event type for all variables and all generators in Figures 3 to 12.

62 **2.4 Pre-FSI events**

63 To investigate why the percentage of MEC events for some generators is low, we performed event selection
64 before any final state interactions took place and plotted the interaction breakdown. For both GENIE tunes,
65 NEUT, and NuWro, we got 100% MEC events pre-FSI. For GiBUU, only 4.1% MEC versus 76.2% RES and
66 16% DIS events pre-FSI. The interaction breakdown for $|\vec{p}_\mu|$ for all the generators are shown in Figure 13.
67 Since GiBUU is the outlier, we checked the specific interaction mode for the resonance events. We got that
68 10 has 39.3%, 11 has 34.7%, 12 has 0.0136%, 13 has 26 %, and 27, 22, and 23 all have zero percent of the
69 resonance events.

70 We also checked the event interaction breakdown for GiBUU samples generated without final state
71 interactions, in which we found that 100% of the events are MEC, shown in Figure 14. Note that the
72 difference between these two GiBUU samples is that in the former, the samples were generated with final
73 state interactions, and then we look at the state before the final state interactions reportedly took place,
74 and in the latter the event generation was done without any final state interactions.

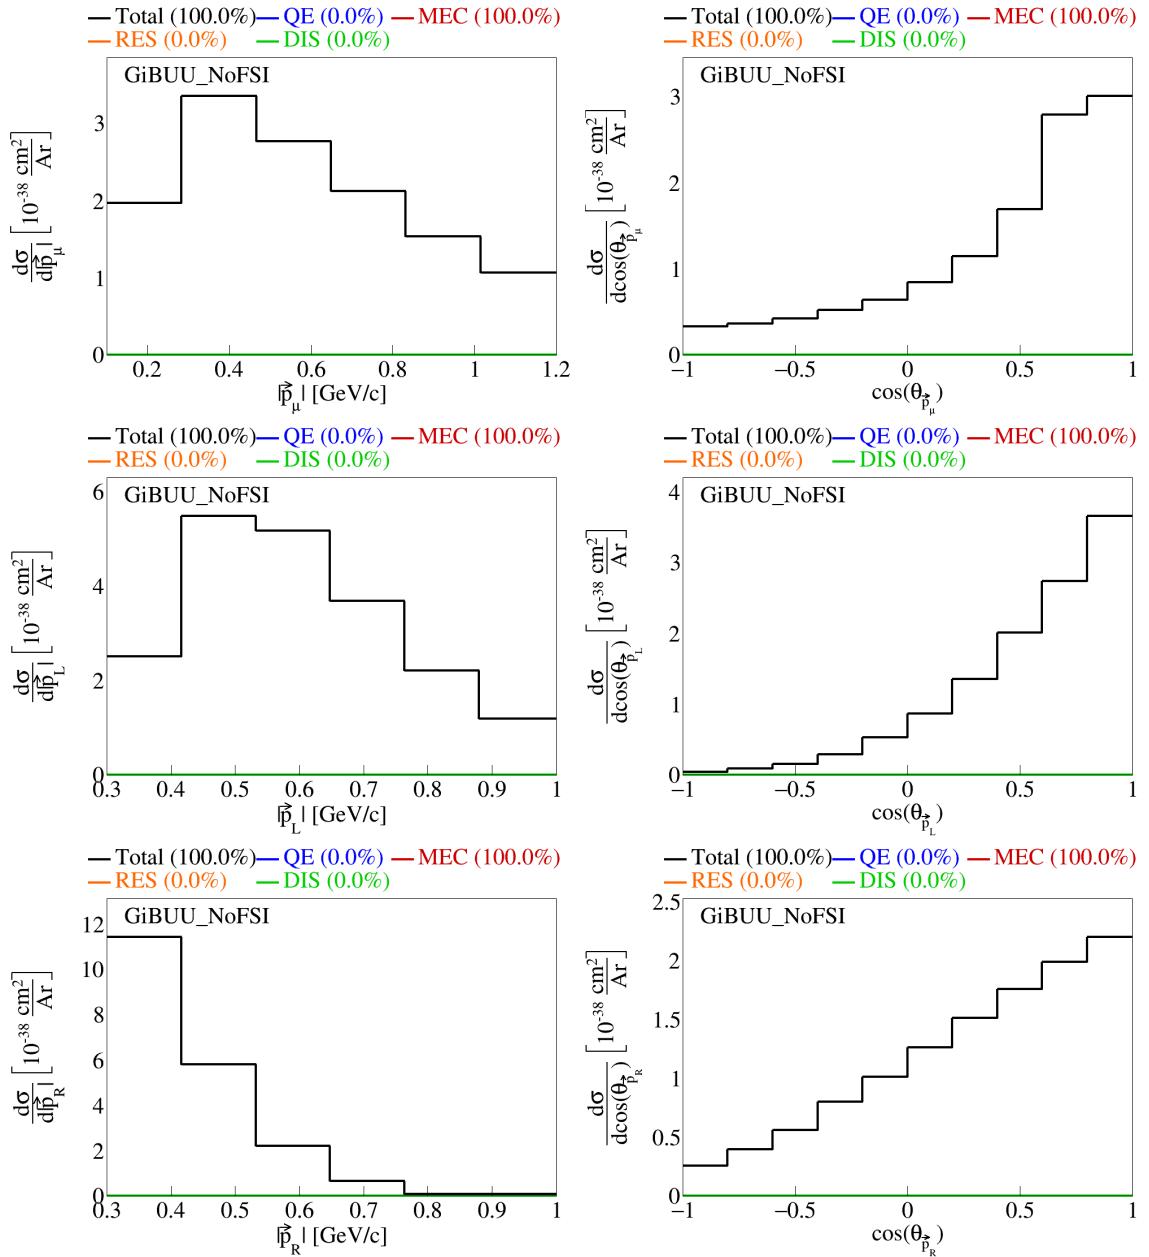

Figure 14: Event interaction breakdown for final events from GiBUU events with no FSI.

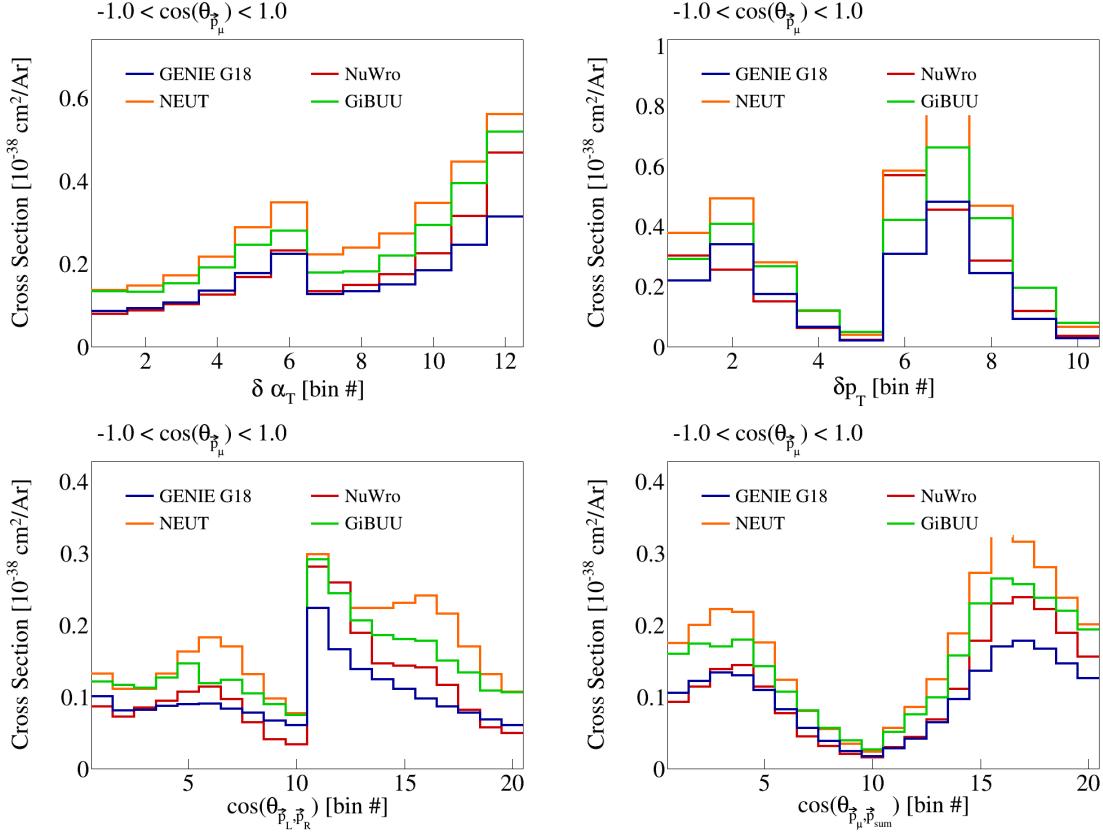

Figure 15: Double differential serial plots, all in $\cos(\theta_{\vec{p}_\mu})$.

75 2.5 Double differential plots

76 We define four double differential variables as δP_T , $\delta \alpha_T$, $\cos(\theta_{\vec{p}_L, \vec{p}_R})$, and $\cos(\theta_{\vec{p}_\mu, \vec{p}_{\text{sum}}})$ in $\cos(\theta_{\vec{p}_\mu})$. We have
 77 two bins for $\cos(\theta_{\vec{p}_\mu})$, the first one going from -1 to 0.5 and the second from 0.5 to 1 . Therefore, these are
 78 irregular bins, with the first covering a larger range than the first. These plots are shown in Figure 15. Note
 79 that, in these plots, the horizontal axis is defined by bin number of the double differential measurement, not
 80 the value of the variable. This is because we are representing both variables in a single axis, but we can slice
 81 the plots to get our usual horizontal axis in two slices of $\cos(\theta_{\vec{p}_\mu})$.

82 We slice the double differential plots into two plots each, so that we have the variable of interest in the
 83 horizontal axis instead of bin numbers, and each slice corresponds to one bin of $\cos(\theta_{\vec{p}_\mu})$. These plots are
 84 shown in Figure 16, and the plots broke down by interaction type are in Figures 17 to 20. In these plots,
 85 the bins contents have been reweighted appropriately, by dividing the content of each bin in the serial plot
 86 by the width of the bin for the variable in the horizontal axis multiplied by the width of the $\cos(\theta_{\vec{p}_\mu})$ slice.
 87 Note that the plots for the $0.5 < \cos(\theta_{\vec{p}_\mu}) < 1$ slice have more events in general, although they span a
 88 smaller phase space of $\cos(\theta_{\vec{p}_\mu})$, as it can be seen by the scale of the vertical axis. We plot the same double
 89 differential variables for the events before final state interactions. These are shown in Figure 21, and the
 90 corresponding interaction breakdown plots are in Figures 22 to 25.

⁹¹ **2.6 Pure MEC events**

⁹² We also generated pure meson exchange current events using different configurations to get the MEC splines.
⁹³ These were all generated using different tunes of GENIE:AR23, G18 with Empirical MEC model, and G18
⁹⁴ with Nieves MEC model. The plots for the transverse kinematic variables are shown in Figures 26 and 27.
⁹⁵ The sliced double differential plots are shown in Figure 28.

96 **3 SBND analysis**

97 The CAF files used for this analysis are available in the Fermilab gpvms at the path

98 `/pnfs/sbnd/persistent/users/twester/sbnd/v09_78_04/cv/*.flat.caf.root`

99 where the asterisk means that all the files in the directory with the extension `.flat.caf.root` will be used.

100 **3.1 Fiducial volume**

101 To perform the analysis of SBND data, we have to define the fiducial volume of the detector, which represents
102 a central part of the detector in which we will accept signals, as:

$$5 < |x| < 180 \quad |y| < 180 \quad 10 < z < 450 \quad (6)$$

103 where x , y , and z are the coordinates in the detector frame, all in centimeters.

104 **3.2 Signal definition**

105 To perform the analysis, we will be using the CAFAna framework. This allows us to perform cuts based
106 on the reconstructed and Monte Carlo data to discriminate events. To discriminate events based on their
107 Monte Carlo data and define our true signal, we perform a simple `TruthCut` that checks the following:

- 108 (i) That the neutrino interaction takes place in the fiducial volume.
- 109 (ii) That the neutrino is a muon neutrino.
- 110 (iii) That the interaction is a charged current interaction.
- 111 (iv) That there is only one muon in our allowed momentum range.
- 112 (v) That there are only two protons in our allowed momentum range.
- 113 (vi) That there are no charged/neutral pions in our defined momenta ranges.

114 Using the reconstructed event data, the cut we have to use is not a simple as in the Monte Carlo data
115 case. We now have to use a `Cut` that looks at different variables of the reconstructed event to determine if
116 it is a signal event. We perform the following cuts to define our reconstructed signal:

- 117 (i) Cosmic: that the event is not a cosmic event by Pandora's criteria, i.e., requiring `nu_score > 0.4` to
118 check how neutrino-like the event is, and `fmatch.score < 7` with $0 < fmatch.time < 1.8$ to check the
119 event comes from the beam.
- 120 (ii) Vertex in FV: that the reconstructed vertex for the neutrino interaction takes place in the fiducial
121 volume defined above.
- 122 (iii) One muon: that there is one muon track with $L_{\text{track}} > 50$ cm, starting point in the fiducial volume,
123 $\chi^2_\mu < 30$, $\chi^2_p > 60$, with momentum in our allowed range; if there are multiple candidate tracks, the
124 one with the longest track length is chosen.
- 125 (iv) Two protons: that there are two proton tracks with $\chi^2_p < 100$, full track in the fiducial volume, and
126 that these have momentum in our allowed range.
- 127 (v) No charged pions: that there are no other reconstructed tracks with momentum in the allowed range
128 for charged pions inside the fiducial volume.
- 129 (vi) No neutral pions: that there are no reconstructed particles with a positive `trackScore` less than 0.5
130 indicating a shower, so we do not allow any neutral pions.

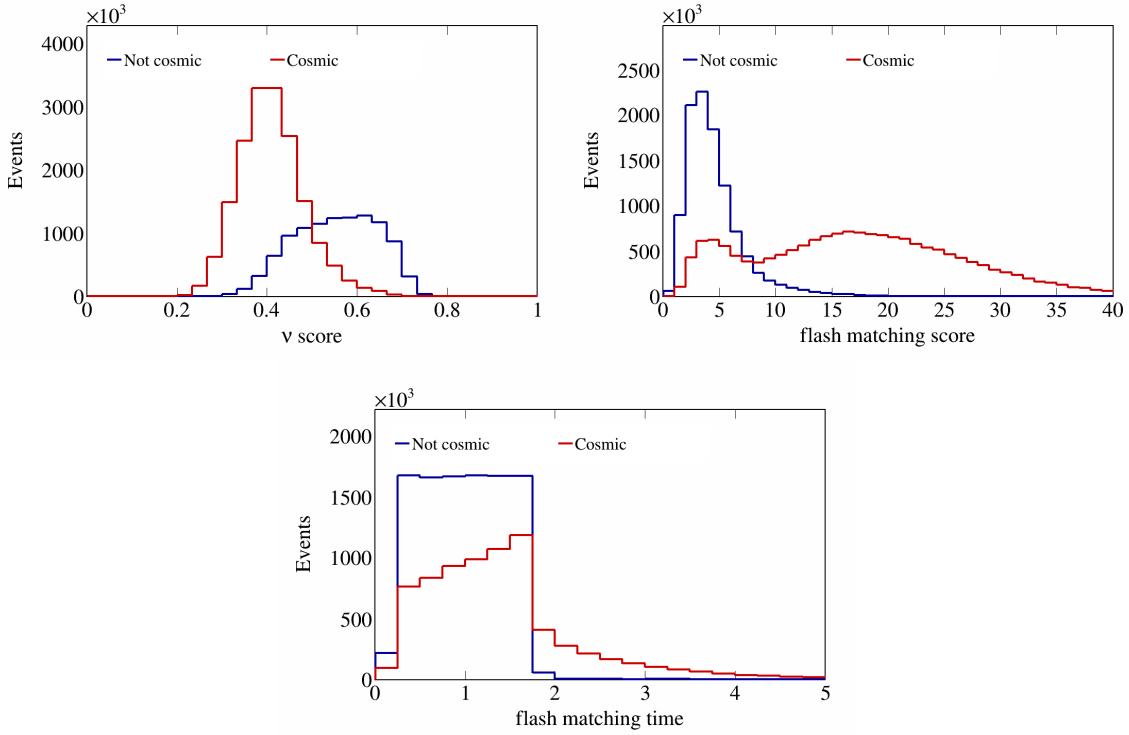

Figure 29: Cosmic cut variables before rejecting cosmic events.

Using these two cuts, we can perform a study of Monte Carlo data. Given the events that pass the reconstructes signal definition, we can look at the background and true signal events. In later sections, we also look at interaction type and topology breakdowns to get a better sense of the composition of our reconstructed signal. To get a better sense of what values the variables chosen to do the cuts take on for each true particle, we plot the flash matching score, time, and ν score in Figures 29, and the χ^2 values for muons and protons in Figure 30.

We use a one-bin histogram to get total counts of generated events, true signal events, all reconstructed events, and efficiency and purity data after each of the cuts described above is applied to the reconstructed events. These results are shown in Table 2. Counts are obtained using ROOT's command `Histo->Integral()` on the histograms generated. Global efficiency is defined as the ratio between events that pass the cut and reconstructed events, signal efficiency as the ratio between true events that pass the cut and all true signal events, and purity as the ratio between true signal events that pass the cut and all events that pass the cut. The numbers reported in this table are POT normalized to 6.79×10^{20} .

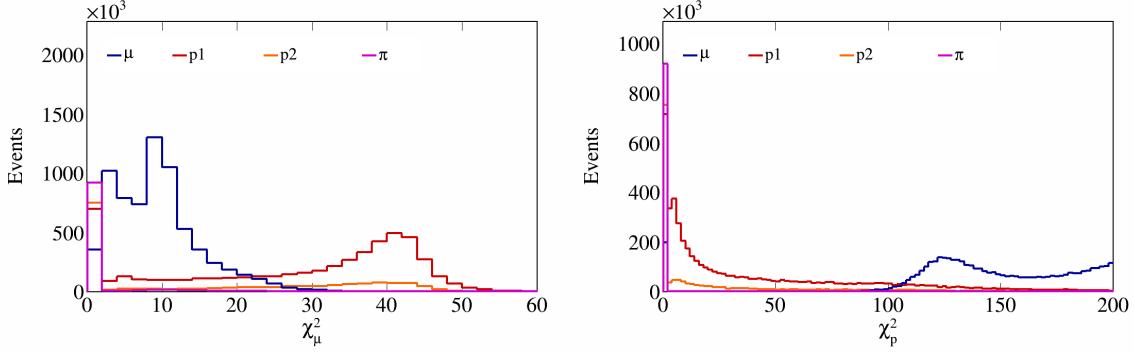

Figure 30: Muon and proton χ^2 values for all particles.

Cut	Number of events	Global efficiency	Signal efficiency	Purity
All	$1.3938 \cdot 10^7$	-	-	-
True signal events	272161	-	-	-
All reco events	$6.82359 \cdot 10^6$	100%	-	-
Cosmic cut	$5.88624 \cdot 10^6$	86.2632%	89.6205%	4.14377%
Vertex in FV cut	$3.29309 \cdot 10^6$	48.2603%	88.2885%	7.29671%
One muon cut	$2.23536 \cdot 10^6$	32.7593%	70.5202%	8.58603%
Two protons cut	146922	2.15315%	17.517%	32.4488%
No charged pions cut	67852.2	0.994377%	12.6665%	50.8065%
No neutral pions cut	54719.5	0.801917%	11.3094%	56.25%

Table 2: Global efficiency, selection efficiency, and purity for cuts made in signal definition.

¹⁴⁴ 3.3 Purity and efficiency studies

¹⁴⁵ Before performing the cross-section extraction, we performed a study of the purity and efficiency of the
¹⁴⁶ slice in the forward direction of the double differential variables. This way, we could ensure that we have
¹⁴⁷ the maximal possible signal contribution, while getting rid of most background events. This is achieved by
¹⁴⁸ maximizing the product of the efficiency and purity. The purity is defined as

$$\text{Purity} = \frac{\text{MC}_{\text{Reco}}^{\text{CC}1p0\pi}}{\text{MC}_{\text{Reco}}} \quad (7)$$

¹⁴⁹ and the efficiency is

$$\text{Efficiency} = \frac{\text{MC}_{\text{Reco}}^{\text{CC}1p0\pi}}{\text{MC}_{\text{True}}^{\text{CC}1p0\pi}} \quad (8)$$

¹⁵⁰ The efficiency, purity, and their product for each cut position in increments of 0.05 are shown in Figure 31.
¹⁵¹ Since we see no major improvement when moving away from 0.5, we maintain the cut at this position. We
¹⁵² do not move the cut to the apparent peak around 0.9 as this would increase the statistical uncertainties in
¹⁵³ the forward slice due to the low number of events that would remain there.

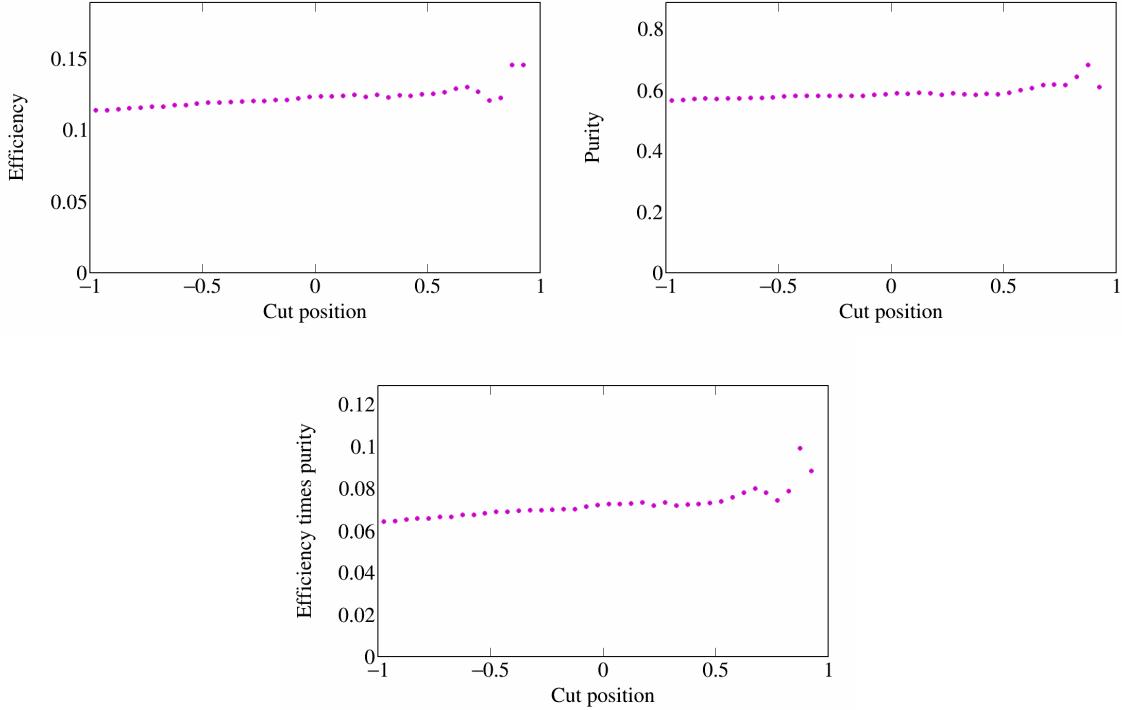

Figure 31: Efficiency and purity of the forward slice at different cut positions for double-differential variables.

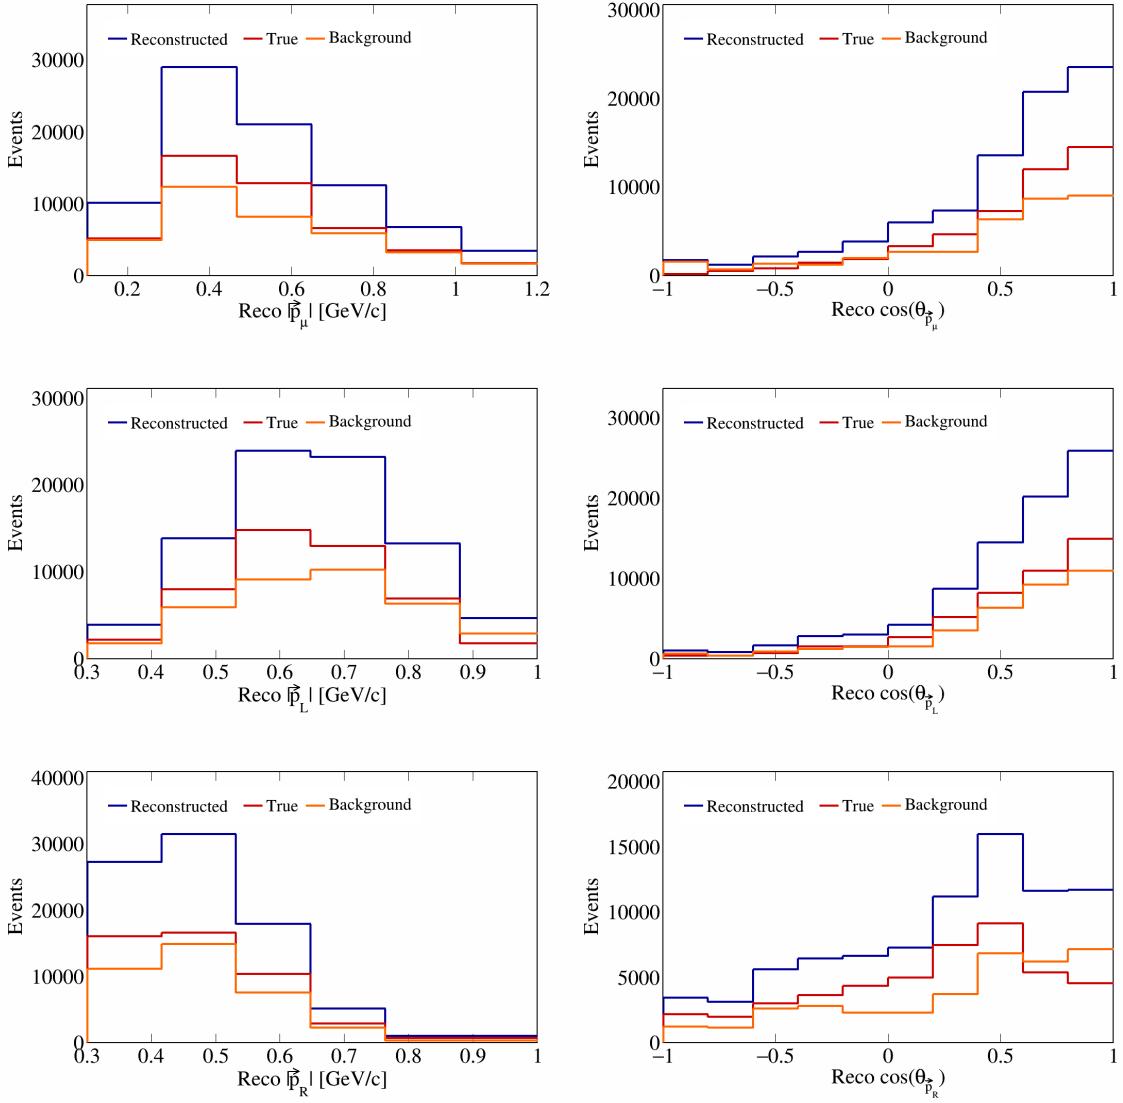

Figure 32: Momenta and opening angles for individual particles for SBND data.

154 3.4 Variable plots

155 Using all the variable definitions as we did when studying the event generators, and the signal definition
 156 based on the cuts described in the previous section, we can generate plots for SBND data. The reconstructed
 157 single differential variables corresponding to vector opening angles and magnitudes are shown in Figure 32.
 158 In these figures, three lines are shown, corresponding to: all reconstructed (all the reconstructed events that
 159 pass our signal definition), signal (reconstructed events that pass signal definition and are true signal events
 160 as determined by the TruthCut from our previous section), and background (reconstructed events that pass
 161 signal definition but are not true signal events) events. Similarly, the variables relating multiple vectors are
 162 shown in Figure 33, and double differential sliced variables are shown in Figure 34.

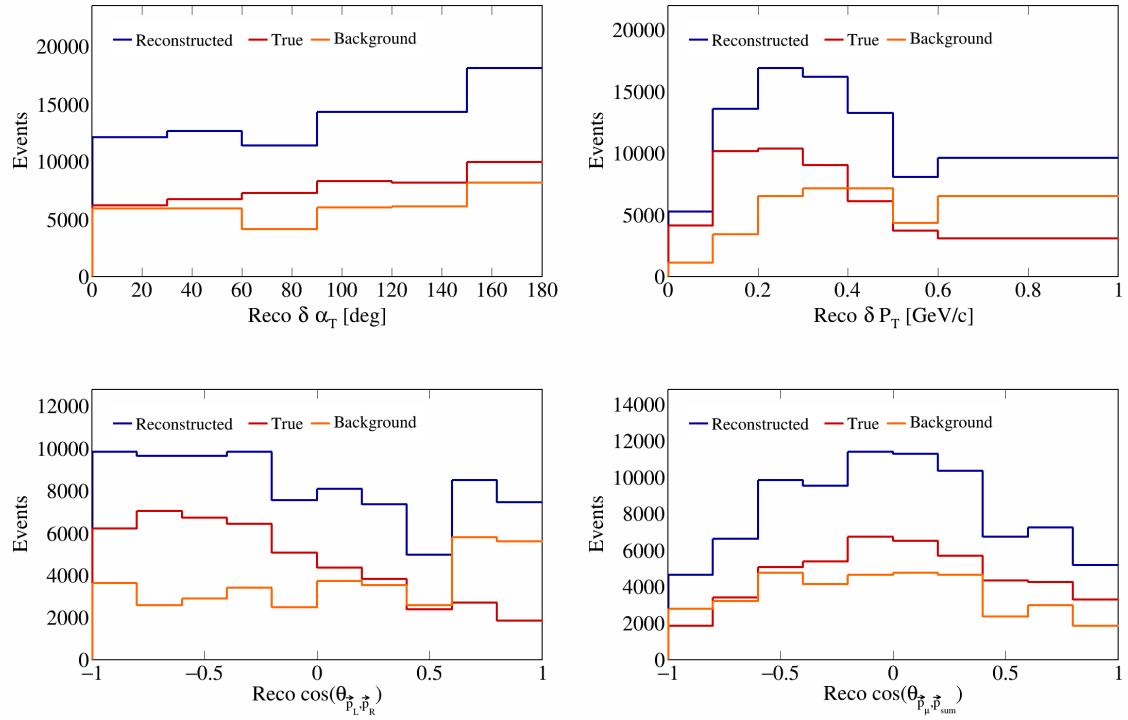

Figure 33: Transverse momentum and opening angles for SBND data.

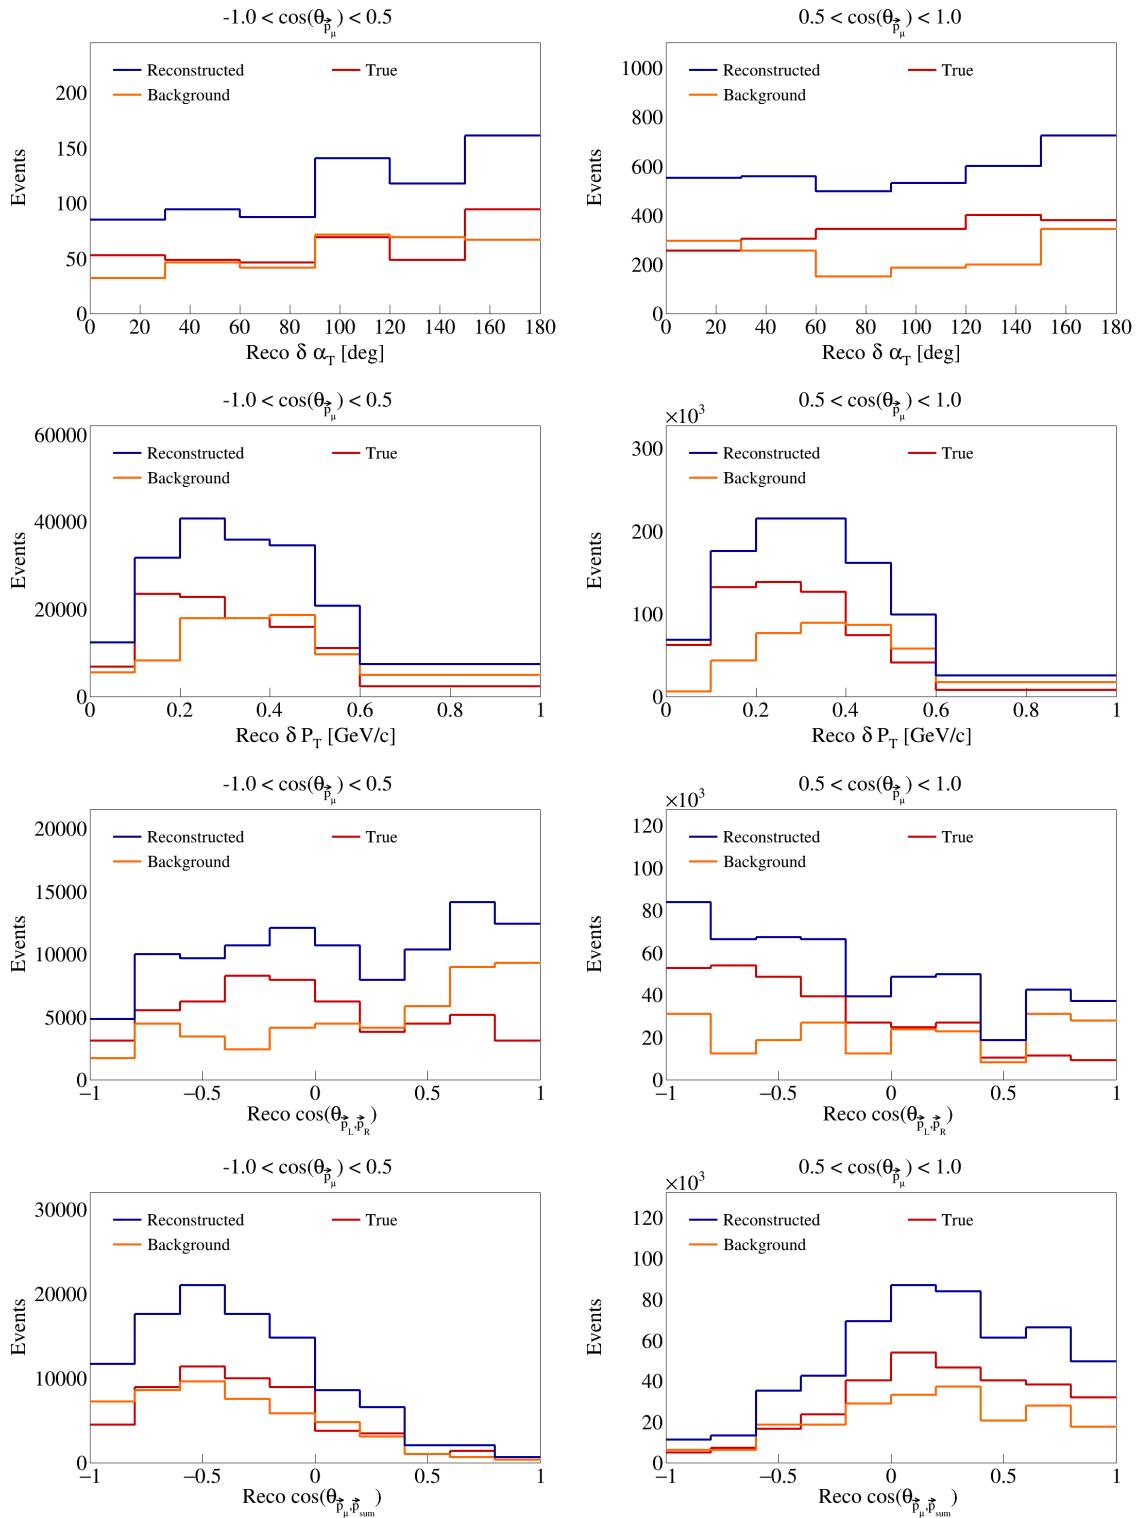

Figure 34: Sliced double differential plots for SBND events.

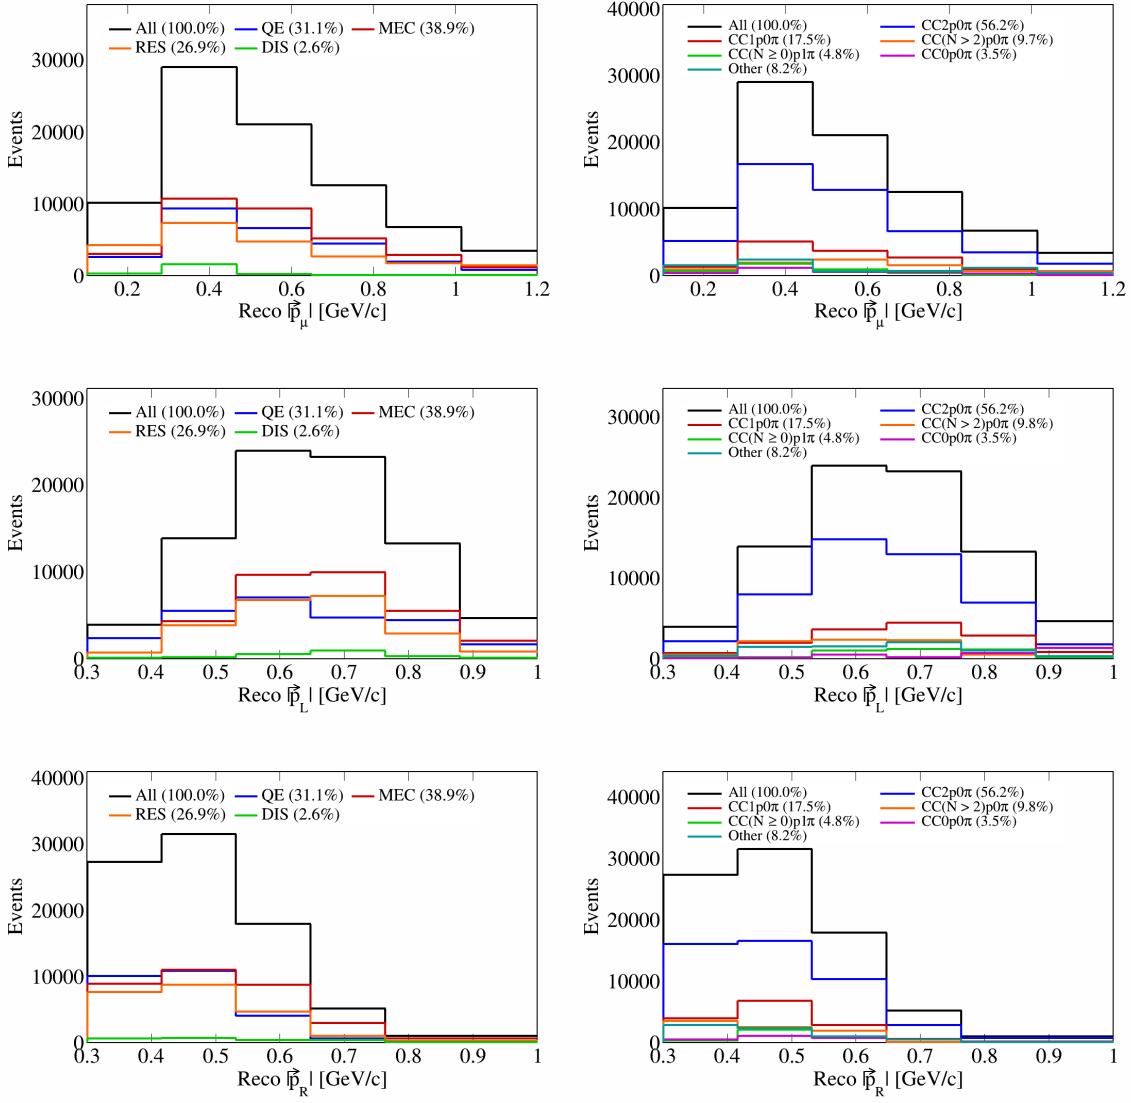

Figure 35: Interaction and topology breakdown for momenta of individual particles.

163 3.5 Interaction and topology breakdown

164 We perform an interaction and topology breakdown for the SBND data. For these breakdowns, we look at
 165 the reconstructed events that pass our signal definitions cuts and see what percentage of these are generated
 166 from different interaction modes and topologies. This helps us get a better idea of what our background
 167 signal is composed of. For the interaction breakdown, we look at quasielastic (QE), MEC (meson-exchange
 168 current), RES (resonance), and DIS (deep inelastic scattering) events. For the topology breakdown, we look
 169 at the number of protons, pions, and muons in the final state. The topologies we label are CC2p0 π (our
 170 signal definition), CC1p0 π , CC(N > 2)p0 π , CC(N ≥ 0)p1 π , and CC0p0 π . Any other event topology is
 171 labeled as “Other”. These breakdowns are shown in Figures 35 to 39.

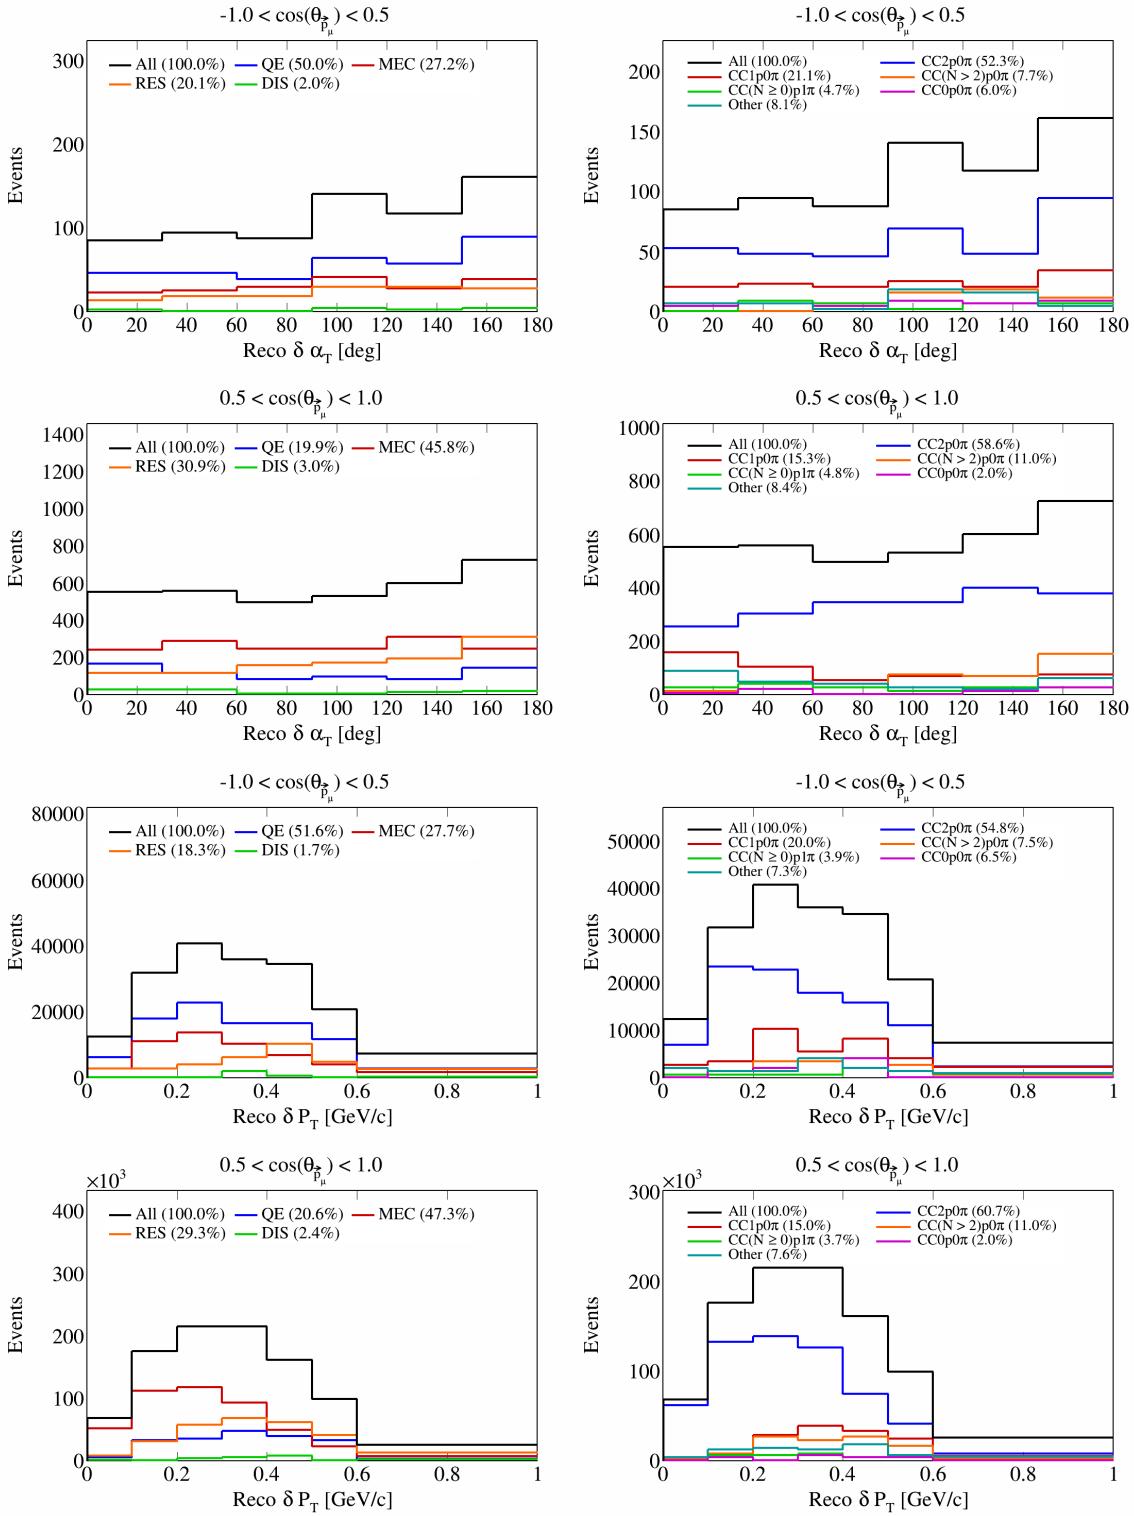

Figure 38: Interaction and topology breakdown for double differential transverse variables.

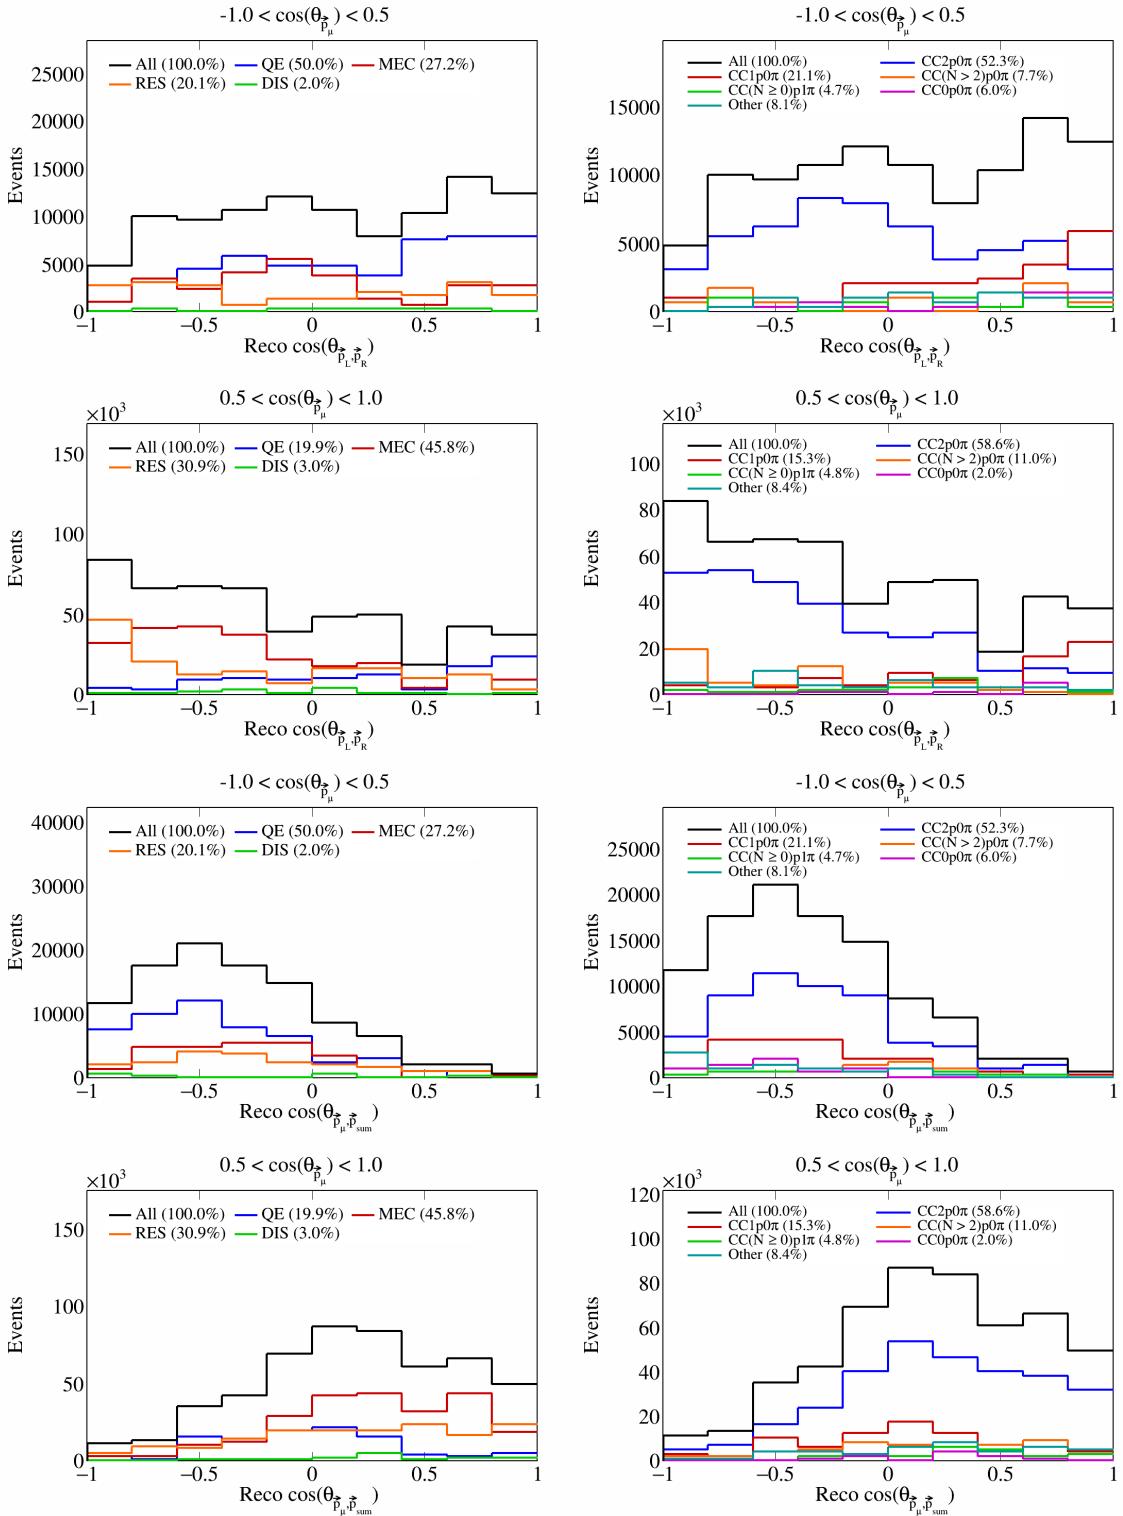

Figure 39: Interaction and topology breakdown for double differential opening angles.

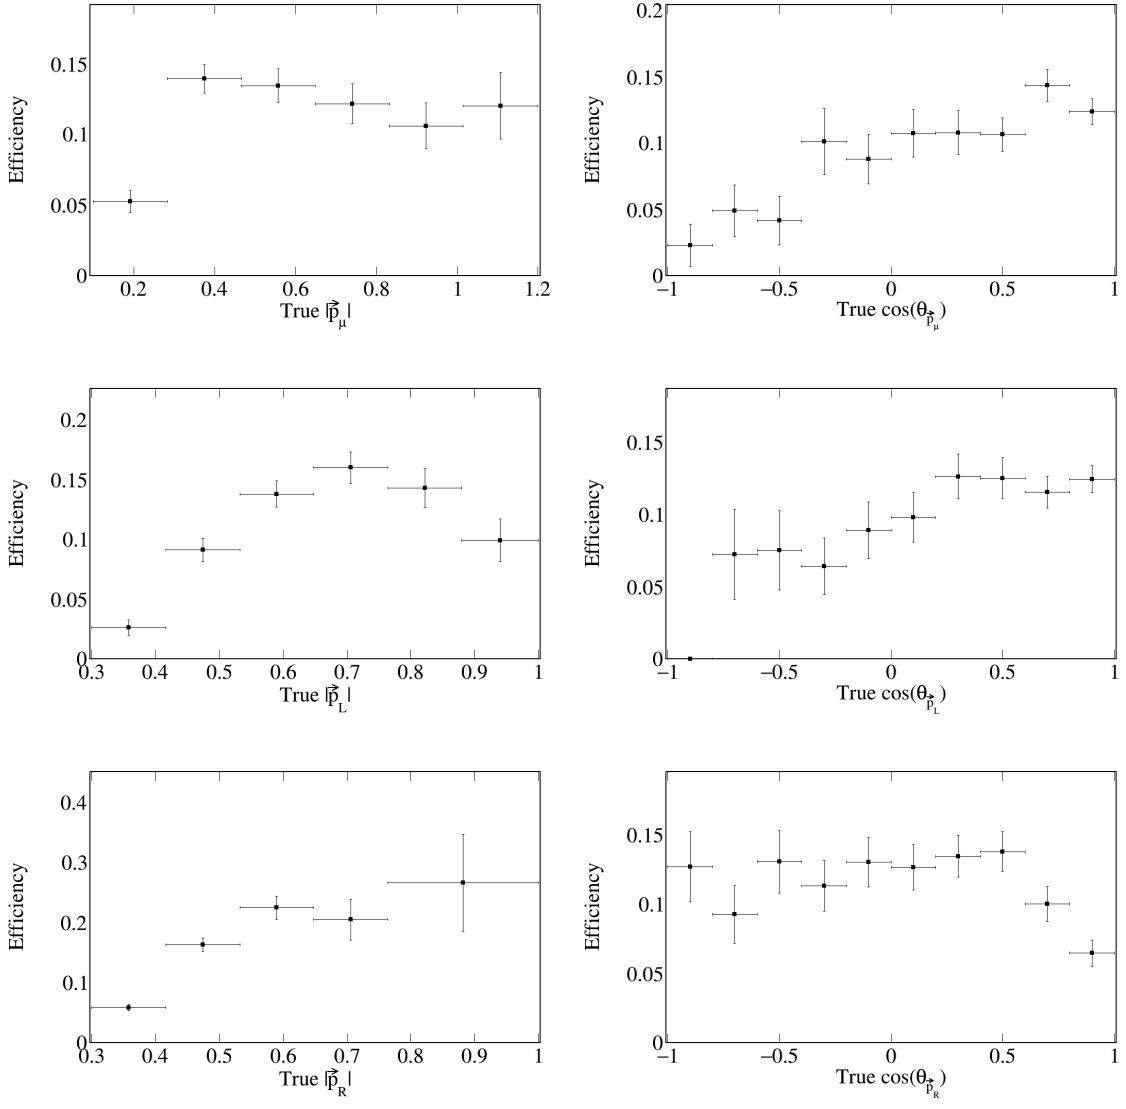

Figure 40: Signal efficiency plots for single differential vector directions and magnitudes.

172 3.6 Signal efficiency

173 Using the truth information about reconstructed events, we can also compute signal efficiency on a bin-by-
 174 bin basis. To be precise, signal definition on a bin i is defined as the ratio between the number of events
 175 generated in bin i and reconstructed in any bin over the number of events generated in bin i . These plots
 176 are shown in Figure 40 and Figure 41 for single-differential variables and Figure 42 for double differential
 177 variables.

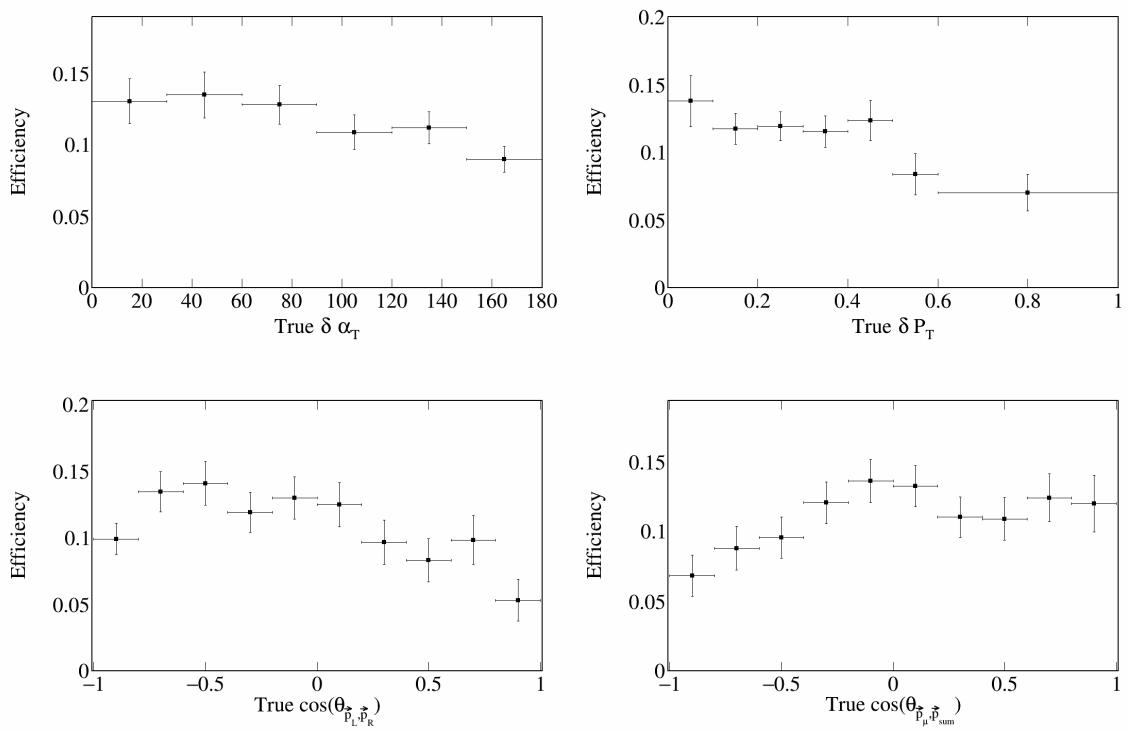

Figure 41: Signal efficiency plots for single differential vector opening angles and transverse momentum.

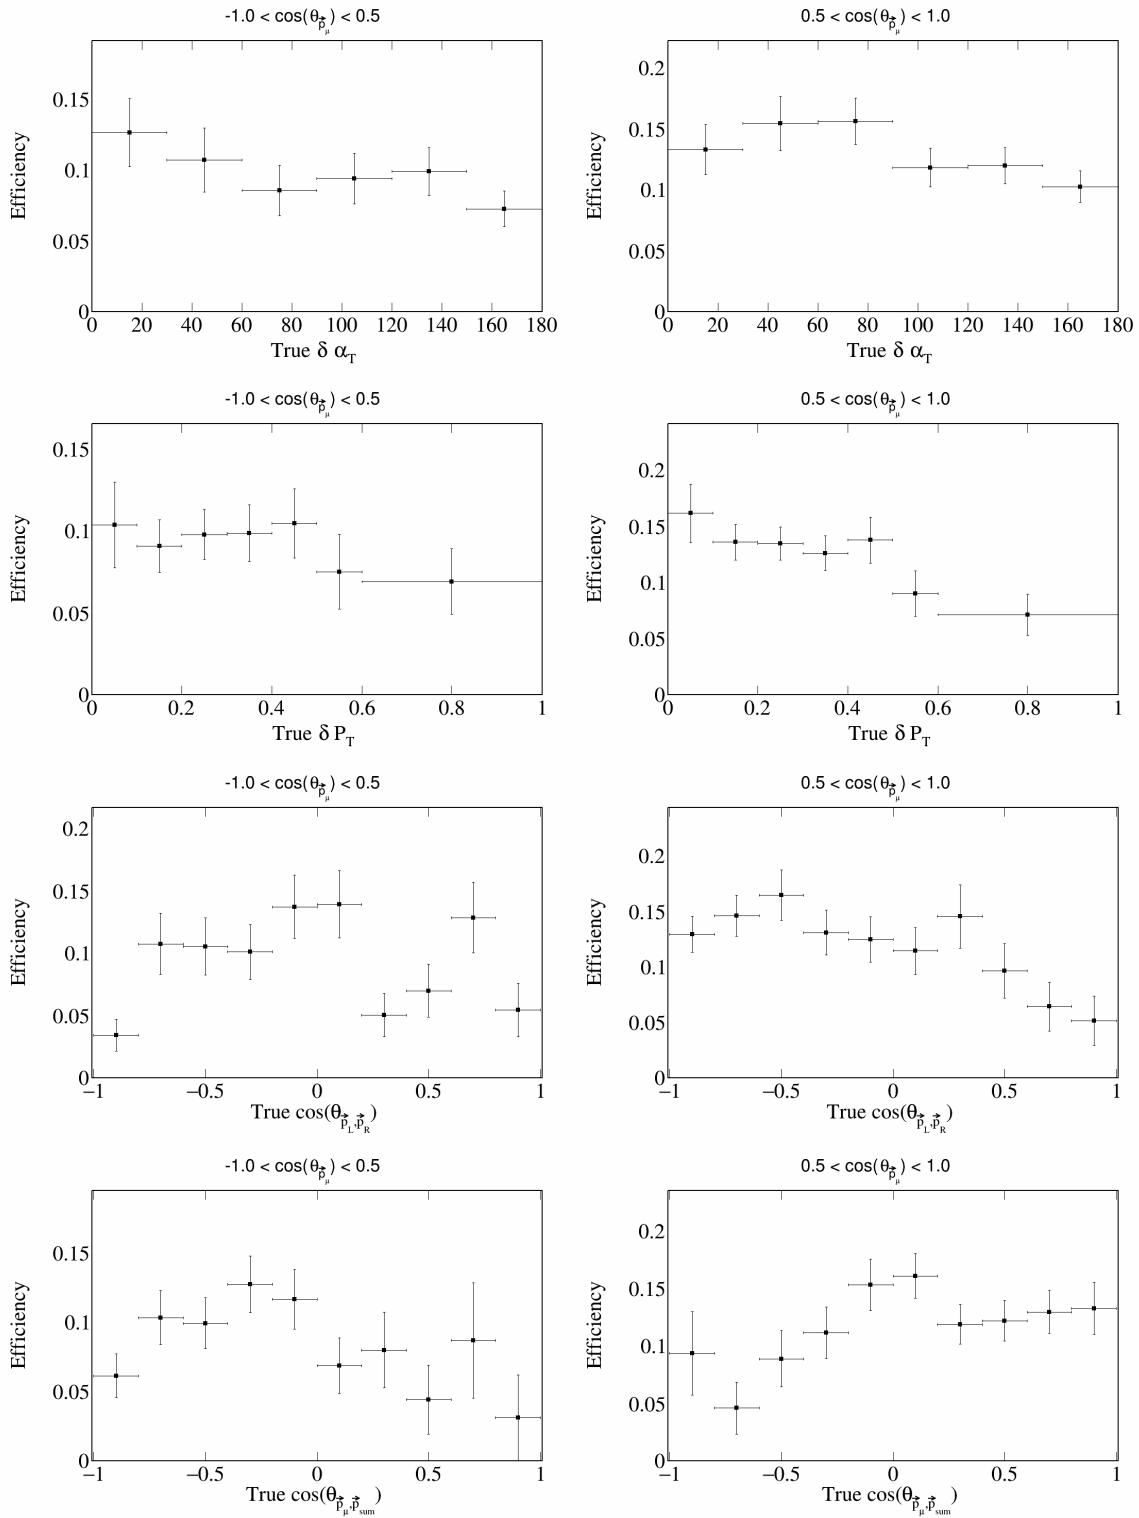

Figure 42: Signal efficiency plots for double differential variables.

¹⁷⁸ **3.7 Migration and response matrices**

¹⁷⁹ Further, we compute migration matrices which give us a measure of how reliable our reconstructed variables
¹⁸⁰ are. A given column in this matrix represents a bin of the truth variable, i.e., the value with which the
¹⁸¹ event was generated. Then, each row corresponds to a reconstructed bin of the same variable, and each cell
¹⁸² corresponds to the probability that an event generated with the truth value corresponding to the column gets
¹⁸³ reconstructed with the value corresponding to the row. For the migration matrix, we consider true signal
¹⁸⁴ events that were reconstructed and satisfy our signal definition in the denominator. Therefore, the values in
¹⁸⁵ each column must add up to 1. The migration matrices for the single differential variables are presented in
¹⁸⁶ Figure 43 and Figure 44. The migration matrices for the double differential variables (given in terms of the
¹⁸⁷ bin number) are presented in Figure 45.

¹⁸⁸ Response matrices are computed in a similar manner, but using the total number of generated events in the
¹⁸⁹ denominator when computing the ratios, i.e., without requiring the events to be successfully reconstructed.
¹⁹⁰ Therefore, for these matrices, the columns of the response matrices do not have to add up to 1. The response
¹⁹¹ matrices for single differential variables are presented in Figure 46 and Figure 47, and the double differential
¹⁹² response matrices are given in Figure 48. A mathematical definition of the response matrix is given in
¹⁹³ Equation (12).

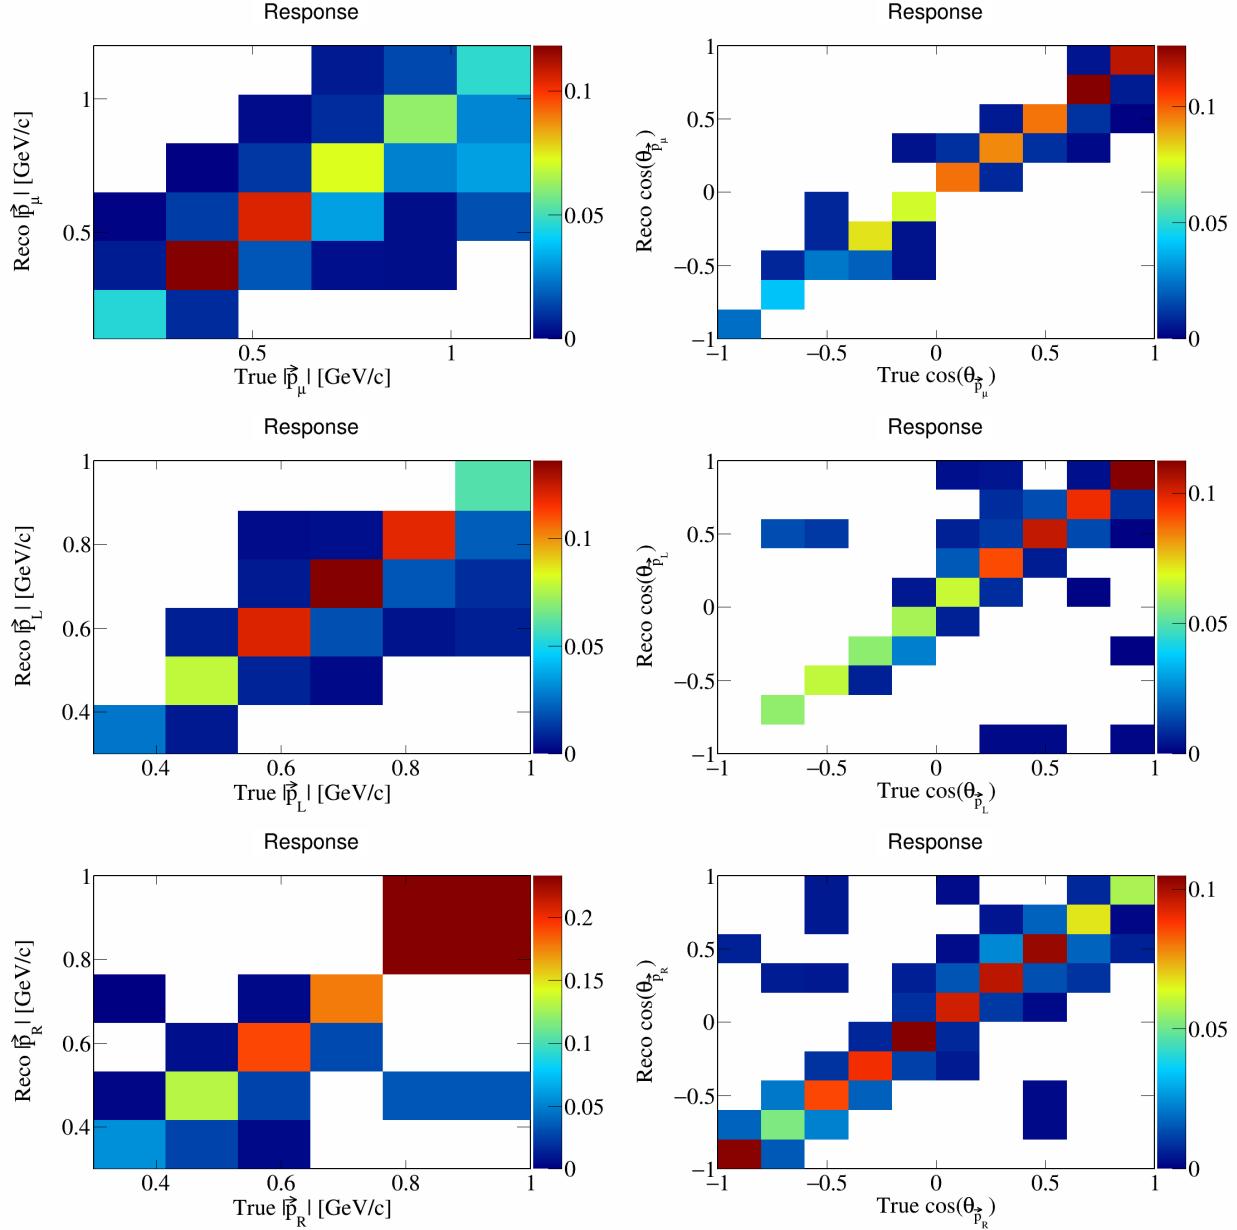

Figure 46: Response matrices for single differential momenta and opening angles of individual particles.

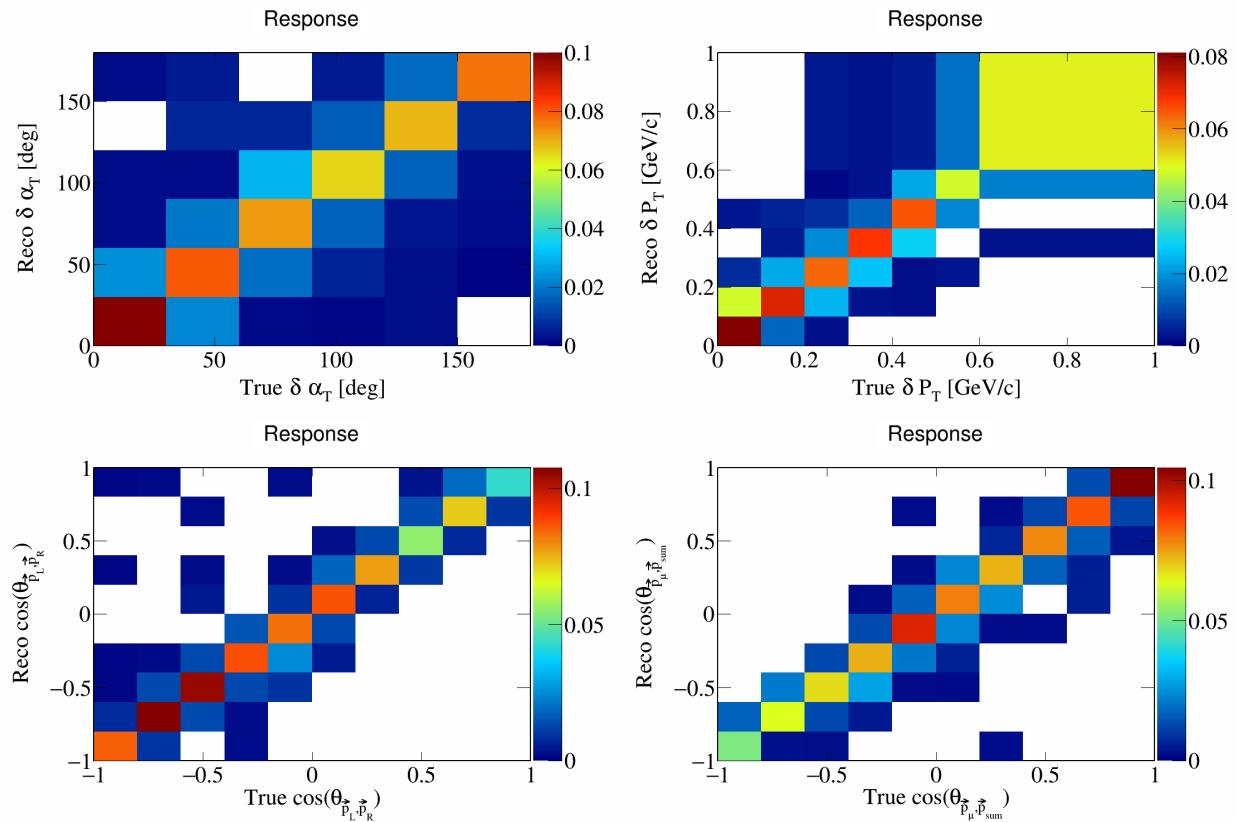

Figure 47: Response matrices for single differential transverse momentum and opening angles.

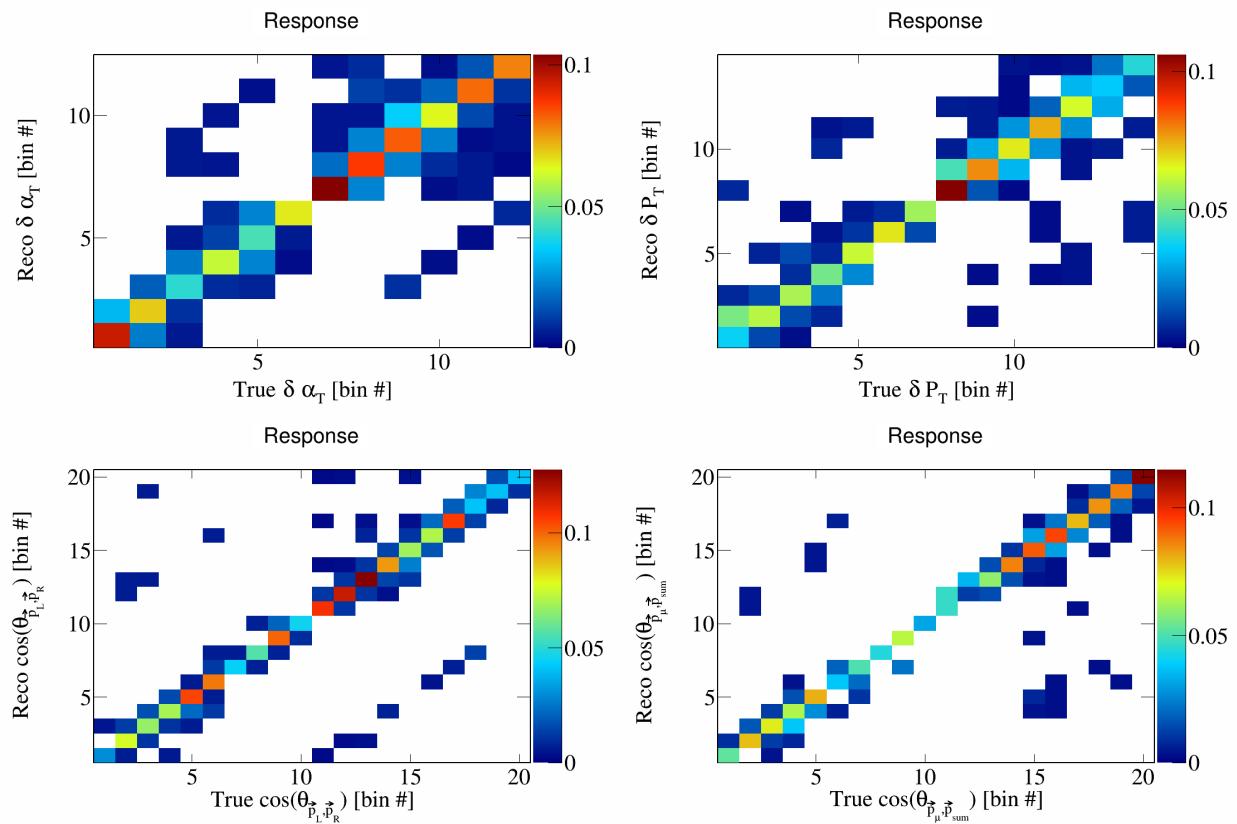

Figure 48: Response matrices for double differential variables.

194 **3.8 Systematics**

195 To include systematic uncertainties in our study, we first consider cross sectional systematics. These are
 196 variations in the cross section models used to generate the events. They can be of two types: multisigma and
 197 multisim. For the former, we consider a 1σ variation of the affected parameters, and in the latter we consider
 198 some number of universes, each with a random variation picked from a Gaussian distribution between 0σ
 199 and 1σ . These weights are already preloaded in the event data file, so we only have to load them into our
 200 script and use them to compute the relevant quantities. From these variations, we compute the covariance
 201 matrix as

$$E_{i,j} = \frac{1}{N_{\text{Univ}}} \sum_{s=1}^{N_{\text{Univ}}} (\tilde{\sigma}_i^{\text{Var},s} - \tilde{\sigma}_i^{\text{CV}})(\tilde{\sigma}_j^{\text{Var},s} - \tilde{\sigma}_j^{\text{CV}}) \quad (9)$$

202 where $\tilde{\sigma}_i^{\text{Var},s}$ represents the variation flux-integrated event rate of the variable in the i -th bin in the s -th
 203 universe, and $\tilde{\sigma}_i^{\text{CV}}$ is the central value (without any variation) of the flux-integrated event rate in the i -th
 204 bin. More formally,

$$\tilde{\sigma}_i = \frac{N^{\text{reco } i}}{\Phi_{\nu}^{\text{CV}} \times N_{\text{targets}}}, \quad (10)$$

205 where $N^{\text{reco } i}$ is the number of reconstructed events in bin i , Φ_{ν}^{CV} is the central value of the neutrino flux
 206 (which remains the same for each variation), and N_{targets} is the number of target Argon nuclei. Further, we
 207 have that $N^{\text{reco } i} = M_{i,j} \times S^{\text{true } j} + B^{\text{reco } i}$, where $M_{i,j}$ is the response matrix corresponding to the true bin j
 208 and reco bin i , $S^{\text{true } j}$ is the number of true signal events in bin j , and $B^{\text{reco } i}$ is the number of reconstructed
 209 background events in bin i . Therefore, we have that

$$\tilde{\sigma}_i = \frac{M_{i,j}^{\text{univ}} \times S^{\text{true } j \text{ CV}} + B^{\text{reco } i \text{ univ}}}{\Phi_{\nu}^{\text{CV}} \times N_{\text{targets}}}, \quad (11)$$

210 where

$$M_{i,j}^{\text{univ}} = \frac{RS^{\text{true } j, \text{ reco } i \text{ univ}}}{S^{\text{true } j \text{ CV}}}, \quad (12)$$

211 with $RS^{\text{true } j, \text{ reco } i \text{ univ}}$ being the number of signal events generated in bin j and reconstructed in bin i , and
 212 $S^{\text{true } j}$ being the number of signal events generated in bin j . For each variation, terms labeled with univ
 213 are modified according to the variation, and terms labeled with CV remain the same. When considering the
 214 cross-section variations, the response matrix is modified via the normalization to the true signal in a given
 215 universe as

$$M_{i,j}^{\text{univ}} = \frac{RS^{\text{true } j, \text{ reco } i \text{ univ}}}{S^{\text{true } j \text{ univ}}}. \quad (13)$$

216 Then, the fractional covariance matrix is defined as

$$F_{i,j} = \frac{E_{i,j}}{\tilde{\sigma}_i^{\text{CV}} \tilde{\sigma}_j^{\text{CV}}}. \quad (14)$$

217 And the correlation matrix is defined as

$$\rho_{i,j} = \frac{E_{i,j}}{\sqrt{E_{i,i} E_{j,j}}}. \quad (15)$$

218 In the case of a multisigma systematic, $N_{\text{Univ}} = 1$, and for a multisim systematic, this number varies but is
 219 usually 100 or 1000.

220 The plots for all the individual cross sectional systematics are shown in Appendix 7.1. Flux systematics
 221 are computed in the same way, but each universe varies a flux parameter. The corresponding plots for the
 222 individual flux systematics are shown in Appendix 7.2. We also consider statistical systematics. This are

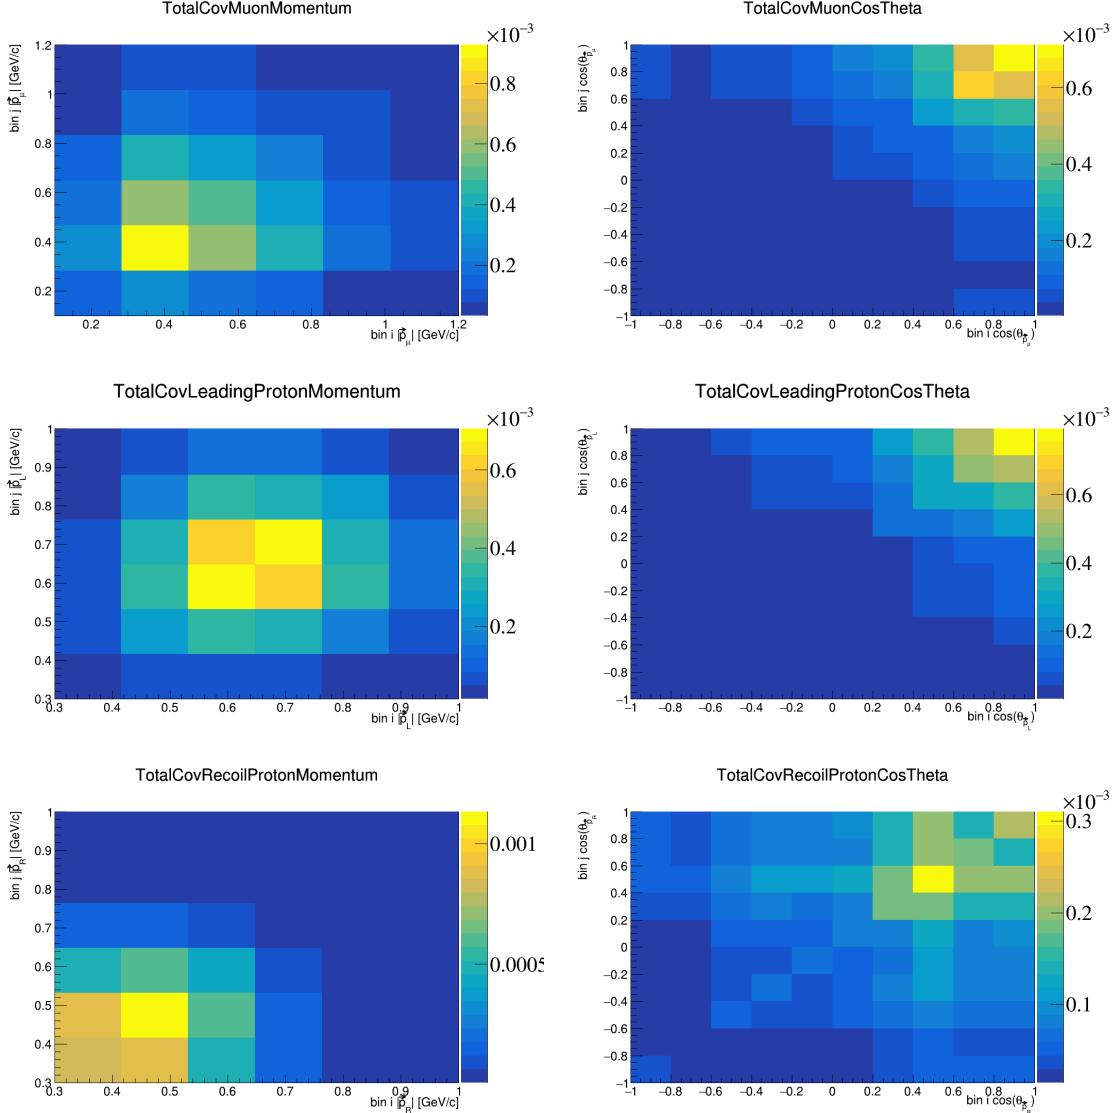

Figure 49: Total covariance matrices for momenta and opening angles of individual particles.

223 straightforward to compute, as the covariance matrix is given by the square root of the number of elements
 224 in the corresponding bin in the histogram. These statistical covariance matrices are shown in Appendix 7.3.
 225 For POT systematics, we consider a 2% variation in the number of protons on target and treat it as a 1σ
 226 variation. The corresponding plots are shown in Appendix 7.4. For number of target systematics, we likewise
 227 consider a 1% variation in the number of target nuclei and treat it as a 1σ variation. The corresponding
 228 plots are shown in Appendix 7.5. We consider detector variations of 15% flat for the moment, and these are
 229 shown in Appendix 7.6. We consider reinteraction systematics as a 2% flat variation, and these are shown
 230 in Appendix 7.7. The total covariance matrices for each variable are shown in Figures 49 to 51.

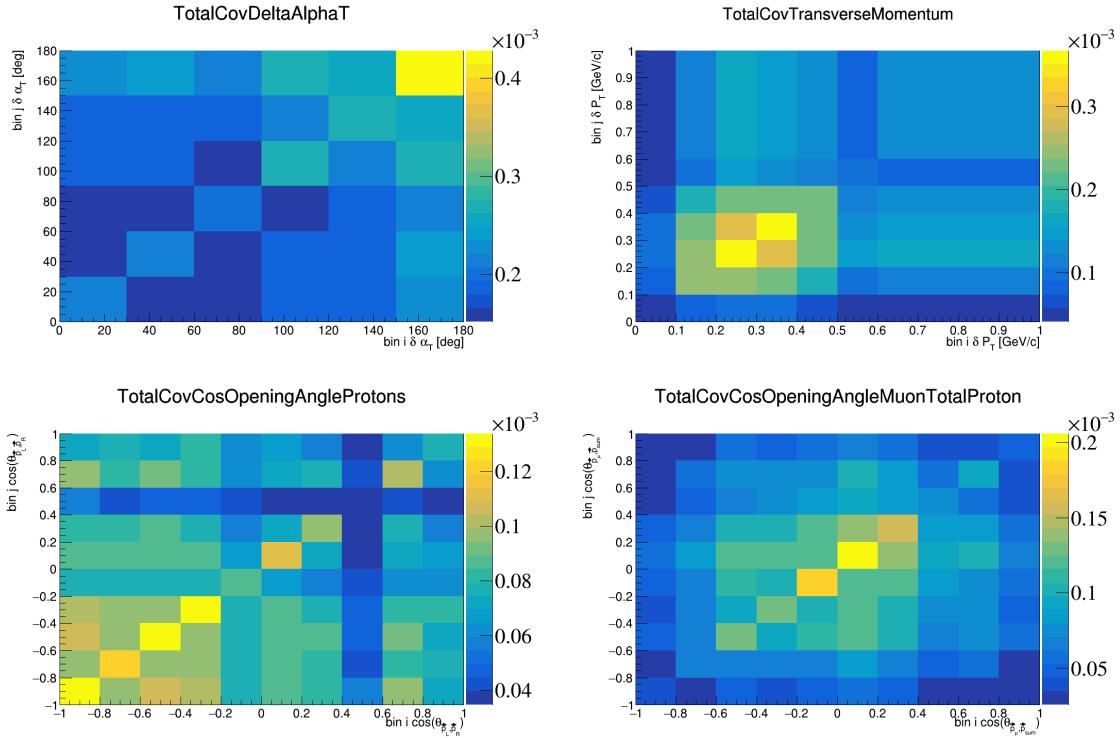

Figure 50: Total covariance matrices for transverse and opening angle variables.

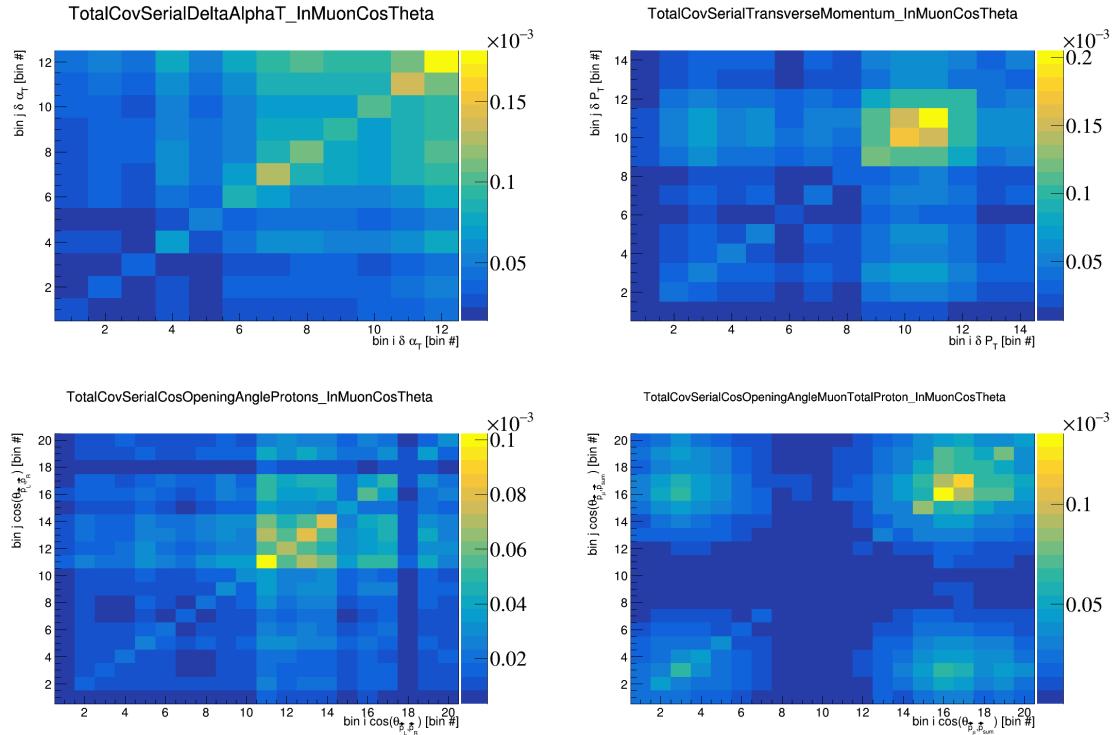

Figure 51: Total covariance matrices for double differential variables.

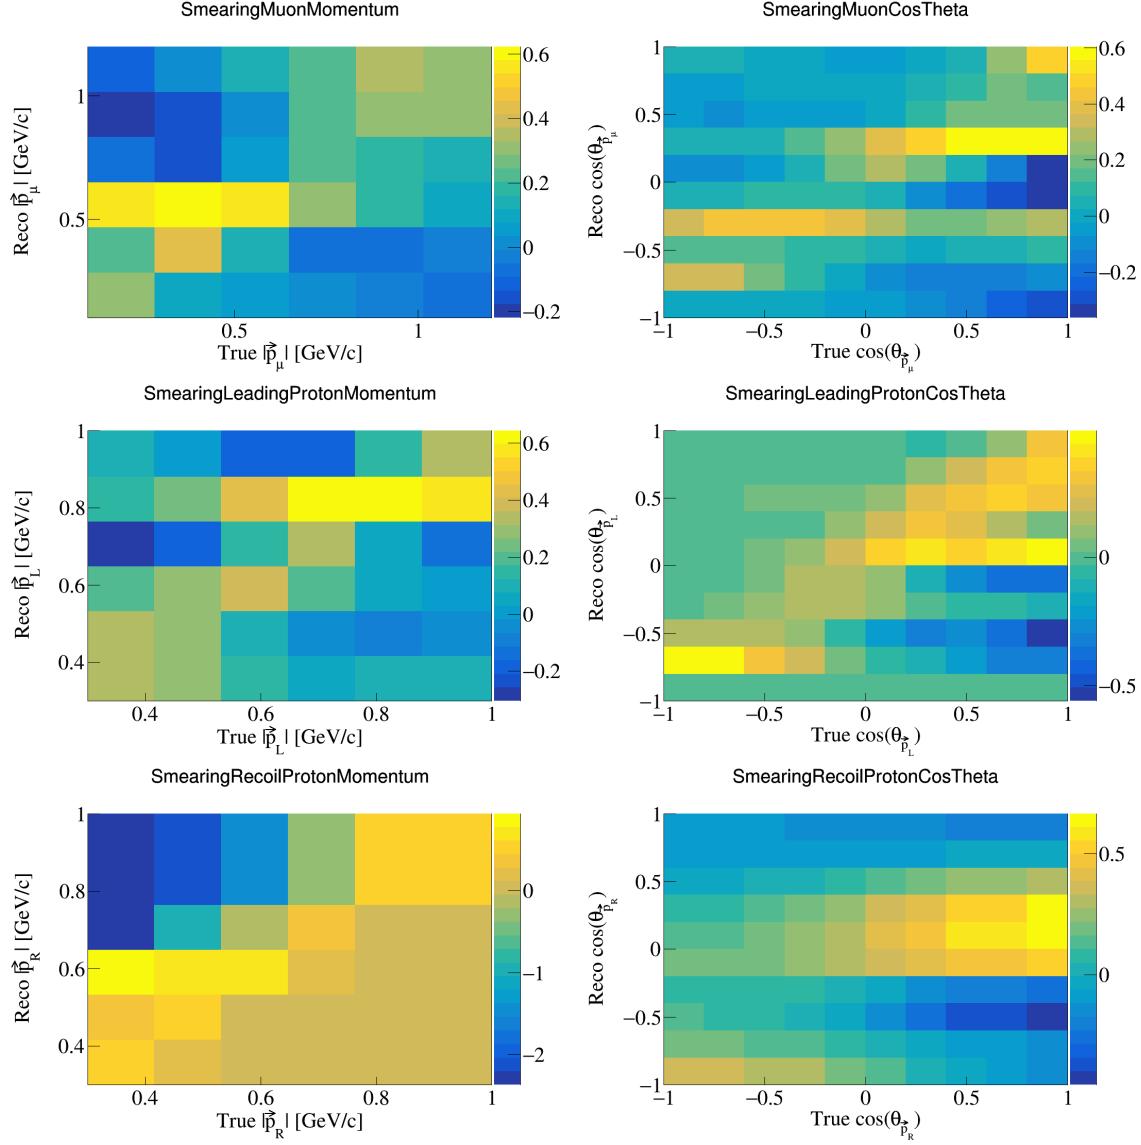

Figure 52: Additional smearing matrices for momenta and opening angles of individual vectors.

3.9 Wiener-SVD unfolding

We use the total covariance matrices obtained from all the systematics and shown in the previous section to unfold our data. We perform this unfolding following the Wiener-SVD method [27], which for a given variable takes as input a response matrix, true signal histogram, a reconstructed signal histogram, and the covariance matrix.

The output is the unfolded spectrum, a smearing matrix that can be used to smear true signal histograms, and a covariance rotation matrix to consider uncertainties in the regularized space as opposed to the true space. The additional smearing matrices obtained from the Wiener-SVD unfolding are shown in Figures 52 to 54.

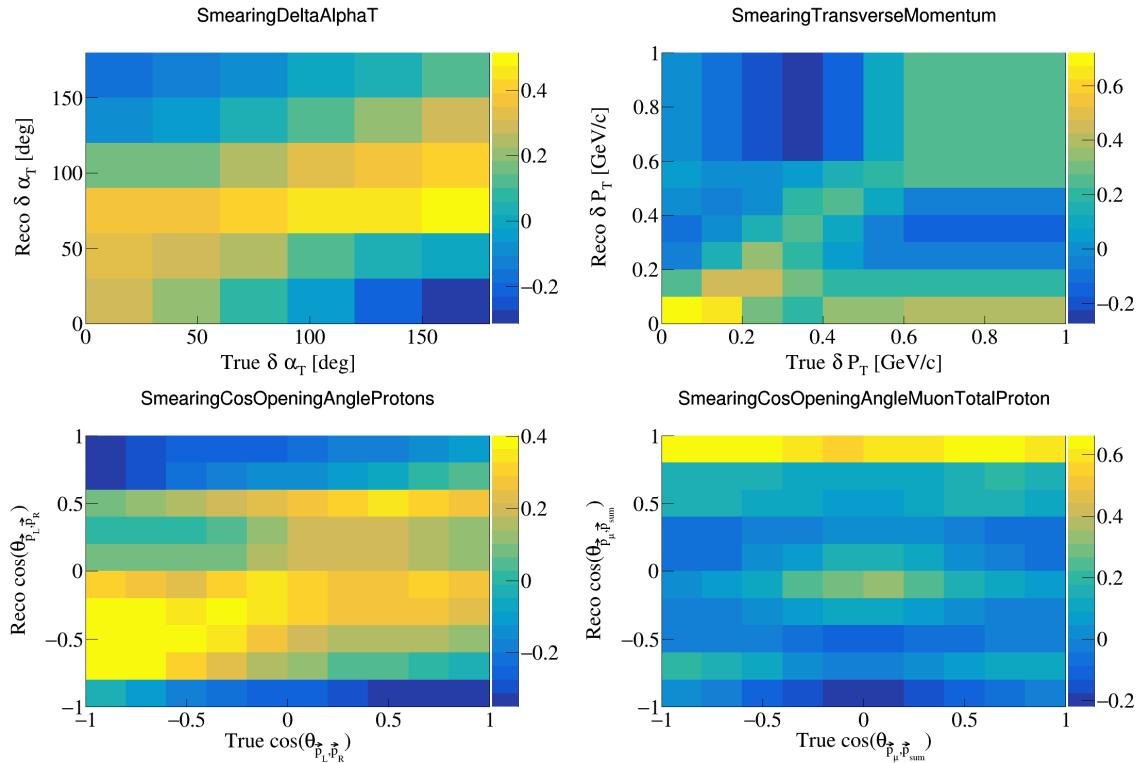

Figure 53: Additional smearing matrices for transverse and opening angle variables.

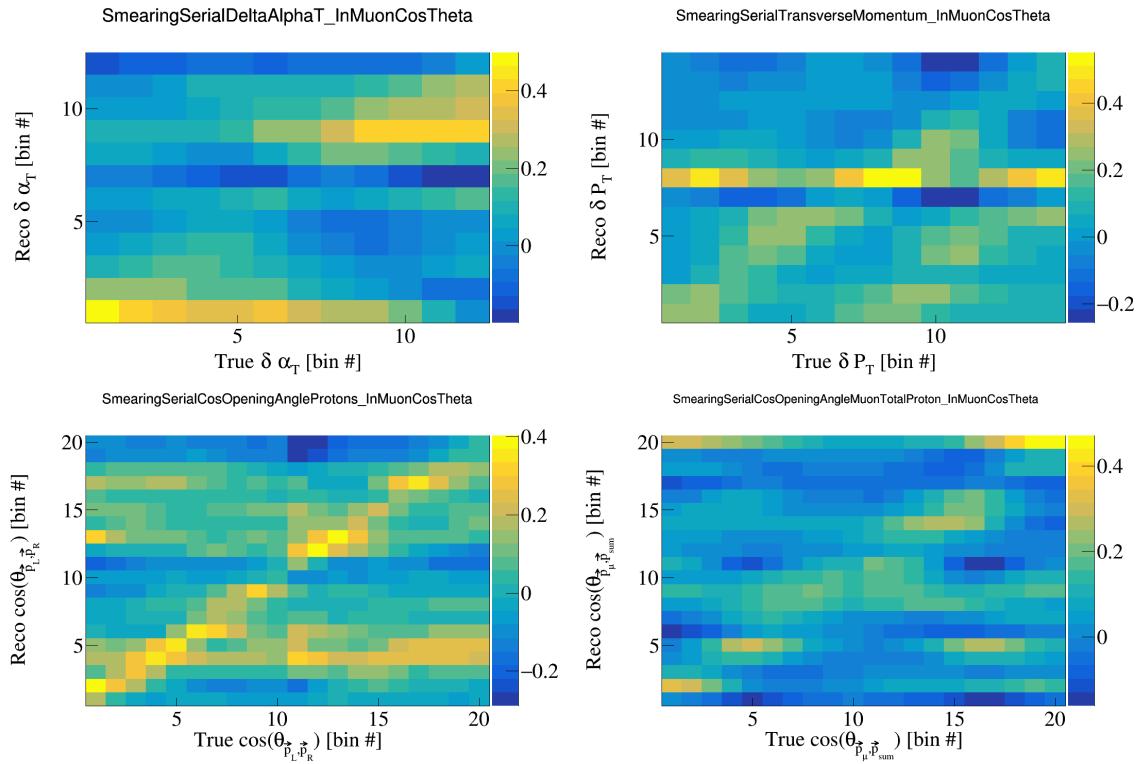

Figure 54: Additional smearing matrices for double differential variables.

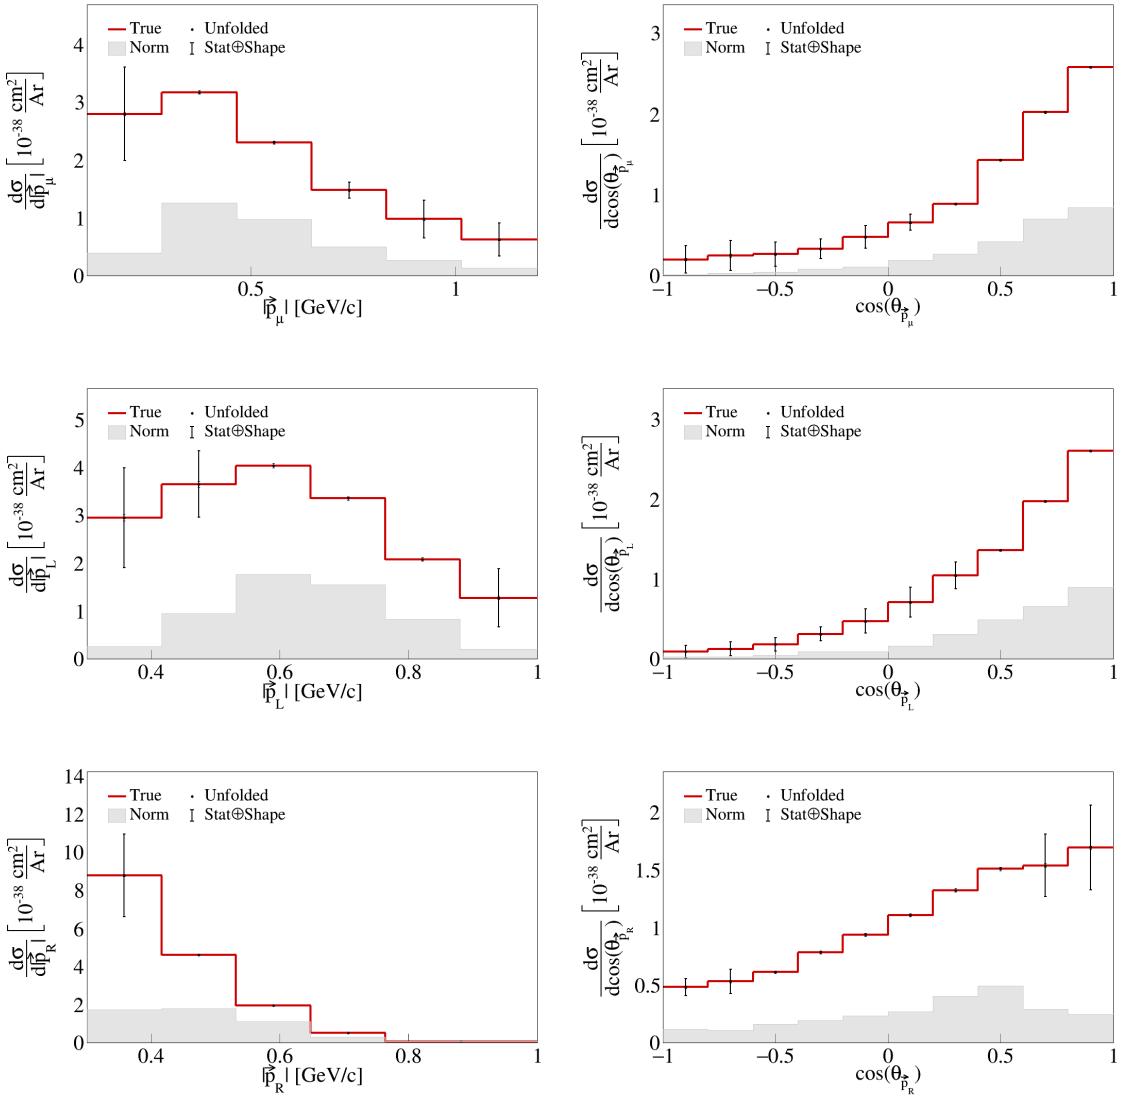

Figure 55: Closure test for momenta and opening angles of individual particles.

240 3.10 Closure test

241 To ensure that the unfolding techniques implemented work correctly, we use the true signal part of our Monte-
 242 Carlo data as our signal, and compare it to the unfolded cross-section obtained from our reconstructed signal
 243 to see that they are identical. The plots showing they are identical are in Figures 55 to 57.

244 The error bands for the unfolded spectra are given by the unfolded total covariance matrices, which
 245 are shown in a bin-by-bin basis in the Section 4.1. For the sliced double differential measurements, we
 246 make sure to divide by the slice and bin widths to obtain the correct error bands. In the single differential
 247 measurements, we only have to divide by the bin width.

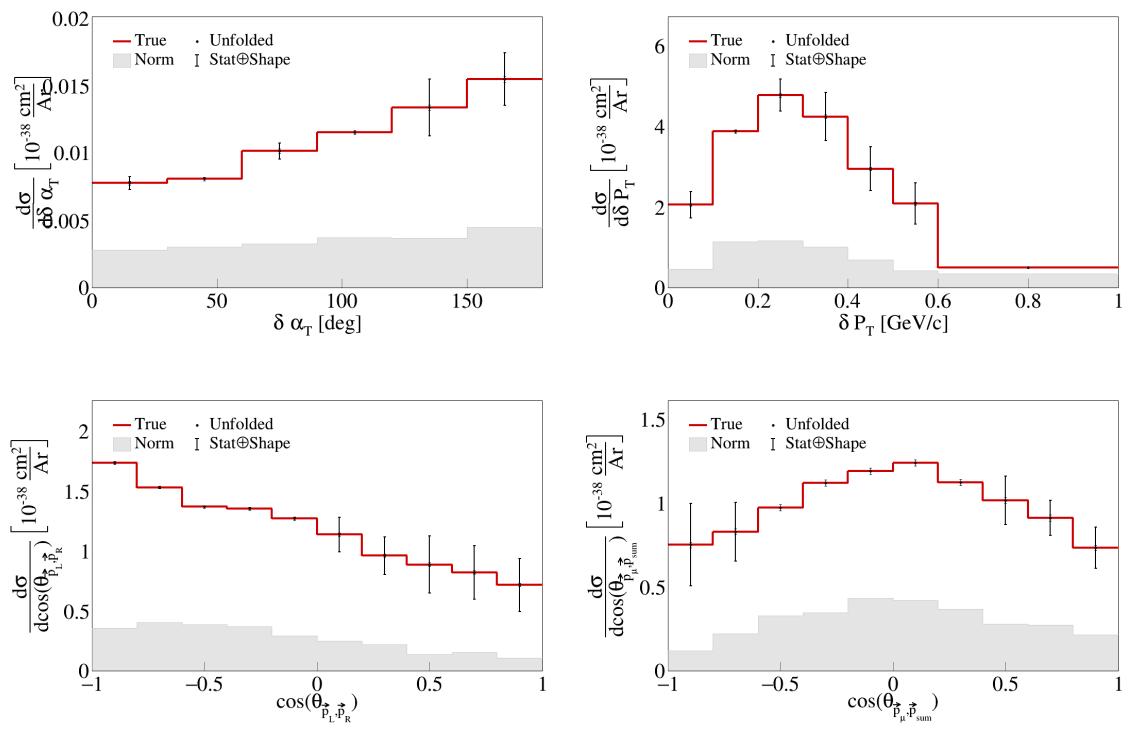

Figure 56: Closure test for transverse and opening angle variables.

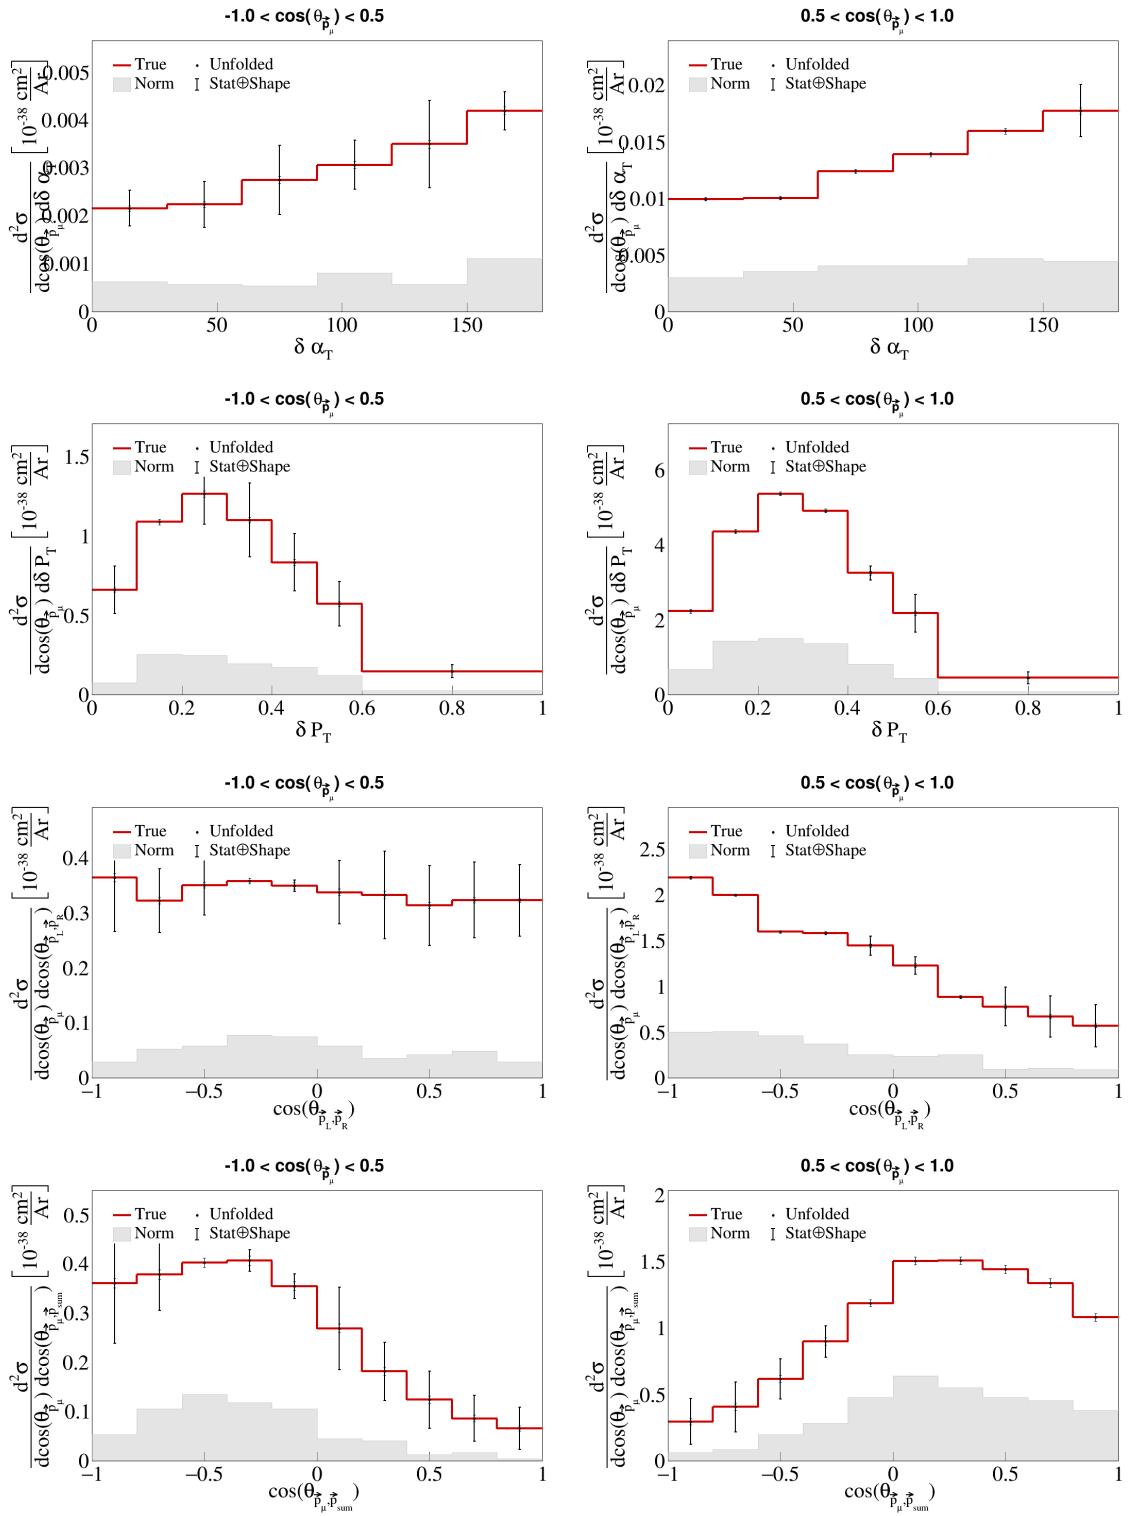

Figure 57: Closure test for double differential plots.

²⁴⁸ **3.11 Event rate uncertainties**

²⁴⁹ Figure 58 shows the single bin uncertainty breakdown using the event rates. We used the square root of
²⁵⁰ the relevant fractional covariance matrix for each of the outlined sources of uncertainty to obtain the figure.
²⁵¹ The bin by bin event rate uncertainties for all our variables are shown in Figures 59 to 61.

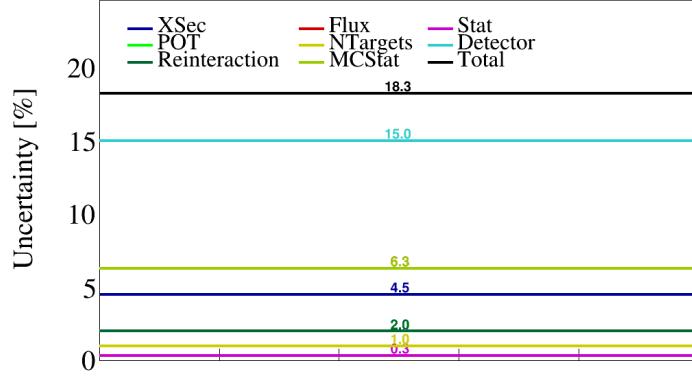

Figure 58: Fractional contribution of the sources of uncertainty using the event rates.

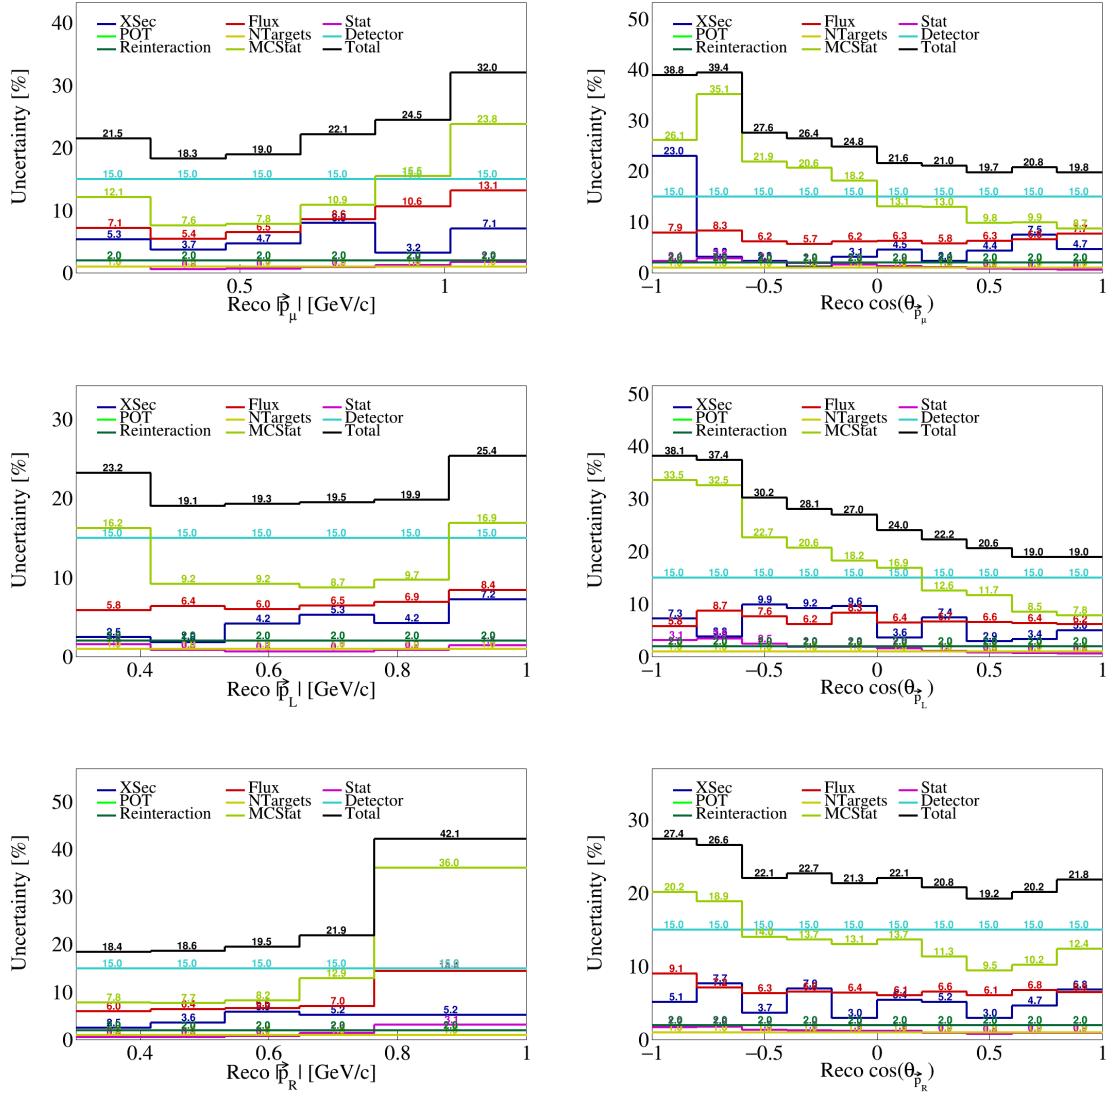

Figure 59: Bin by bin event rate uncertainties for momenta and opening angles of individual particles.

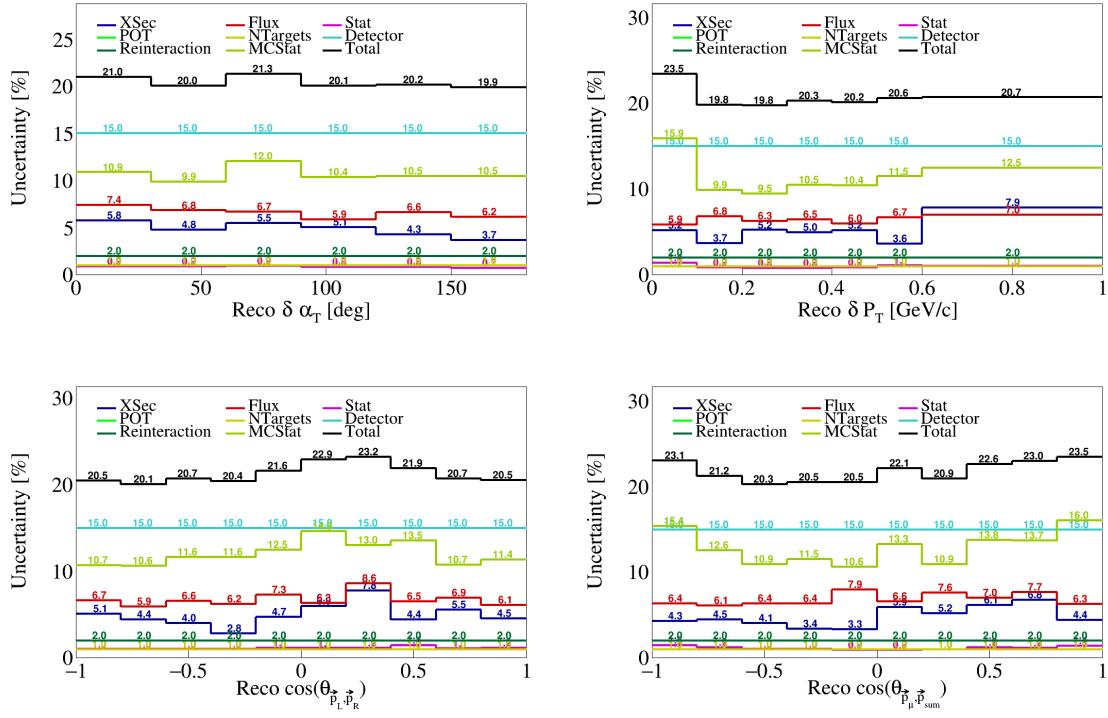

Figure 60: Bin by bin event rate uncertainties for transverse and opening angles variables.

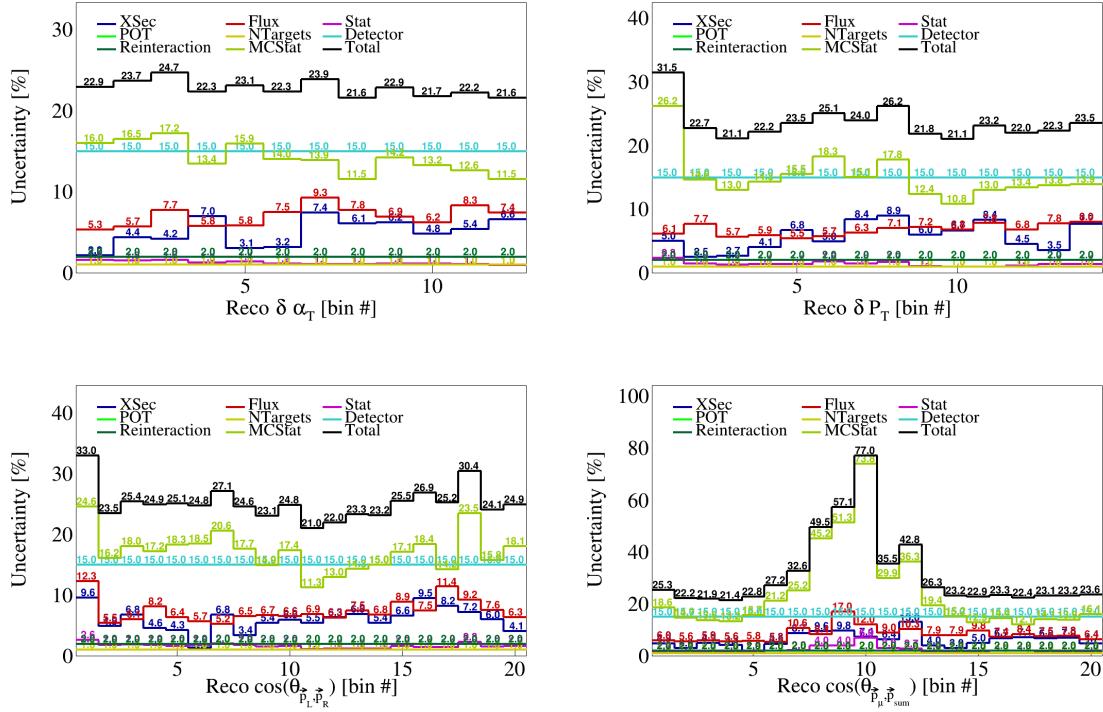

Figure 61: Bin by bin event rate uncertainties for double differential variables.

3.12 Difference and resolution

As a sanity check, we compute the difference and resolution between the reconstructed and the true values for each of our single-differential variables for events that satisfy our signal definition. The difference is defined as

$$x_{\text{Difference}} = x_{\text{reco}} - x_{\text{true}}, \quad (16)$$

while the resolution is defined as

$$x_{\text{Resolution}} = \frac{x_{\text{reco}} - x_{\text{true}}}{x_{\text{true}}}. \quad (17)$$

We expect both distributions to be centered around zero. The distributions are shown in Figures 62 to 64.

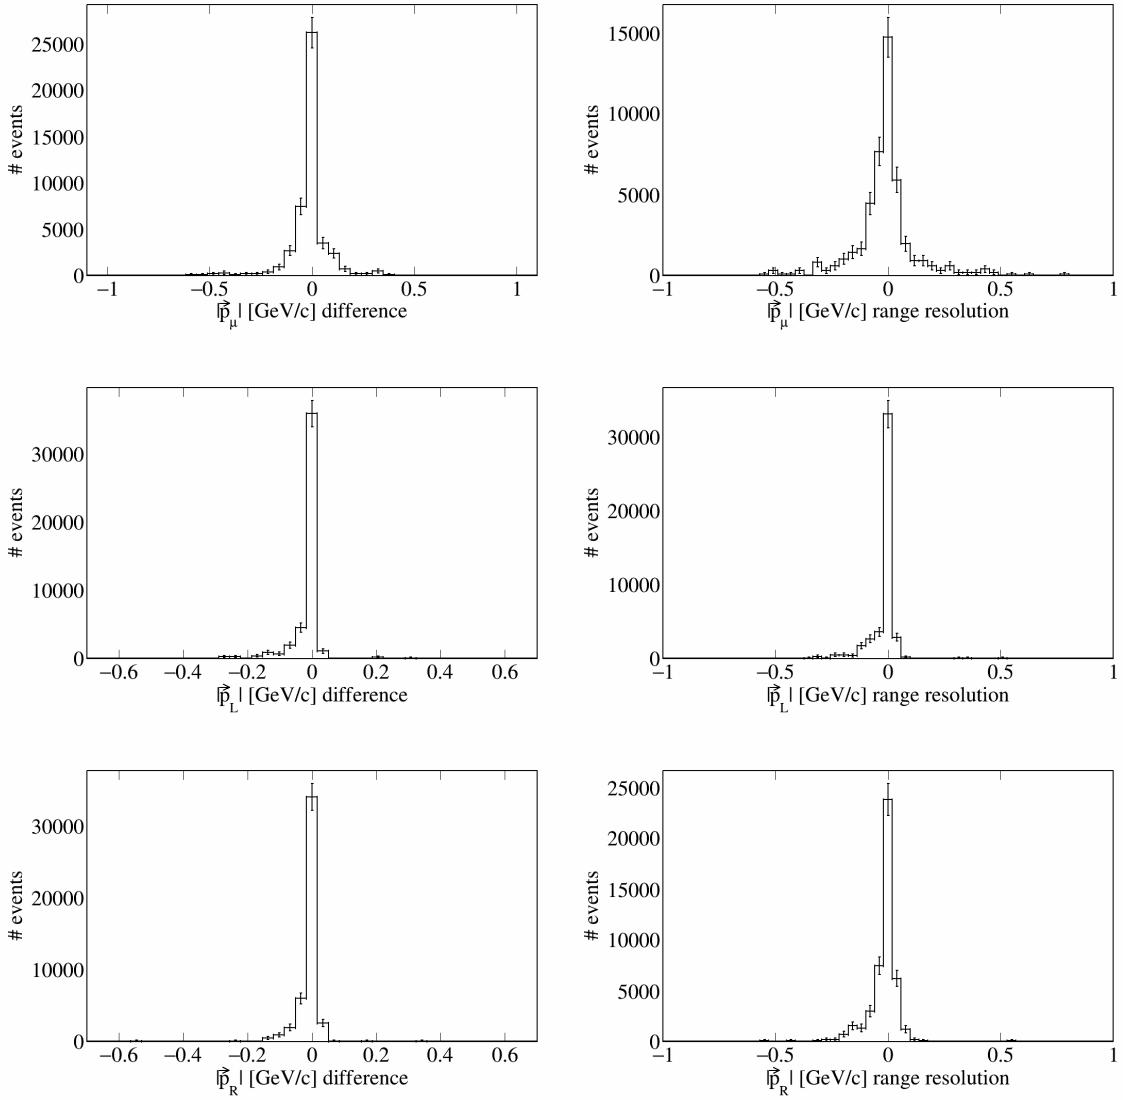

Figure 62: Difference and resolution plots for momenta of individual particles.

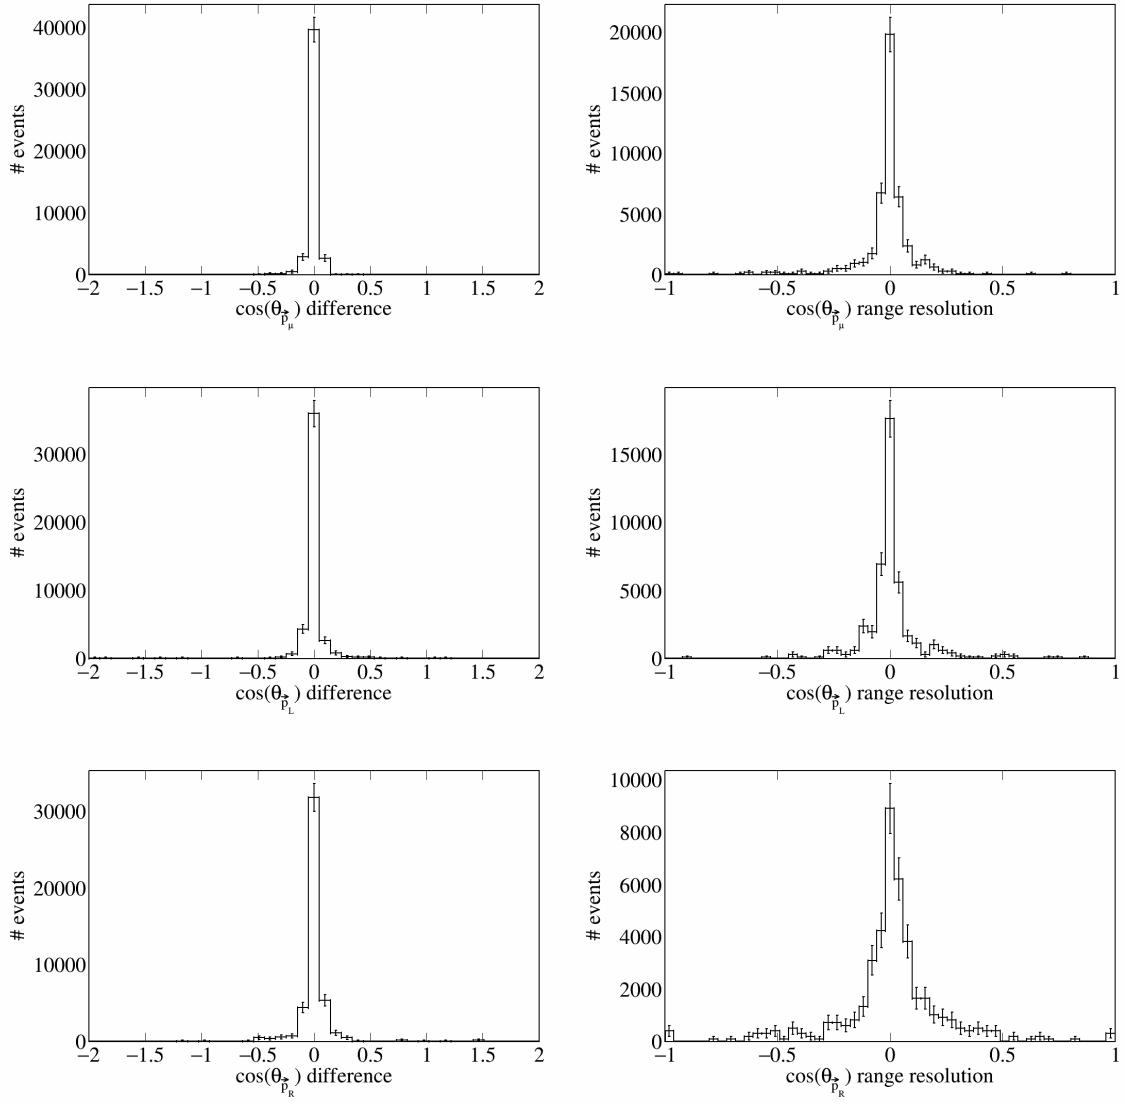

Figure 63: Difference and resolution plots for opening angles of individual particles.

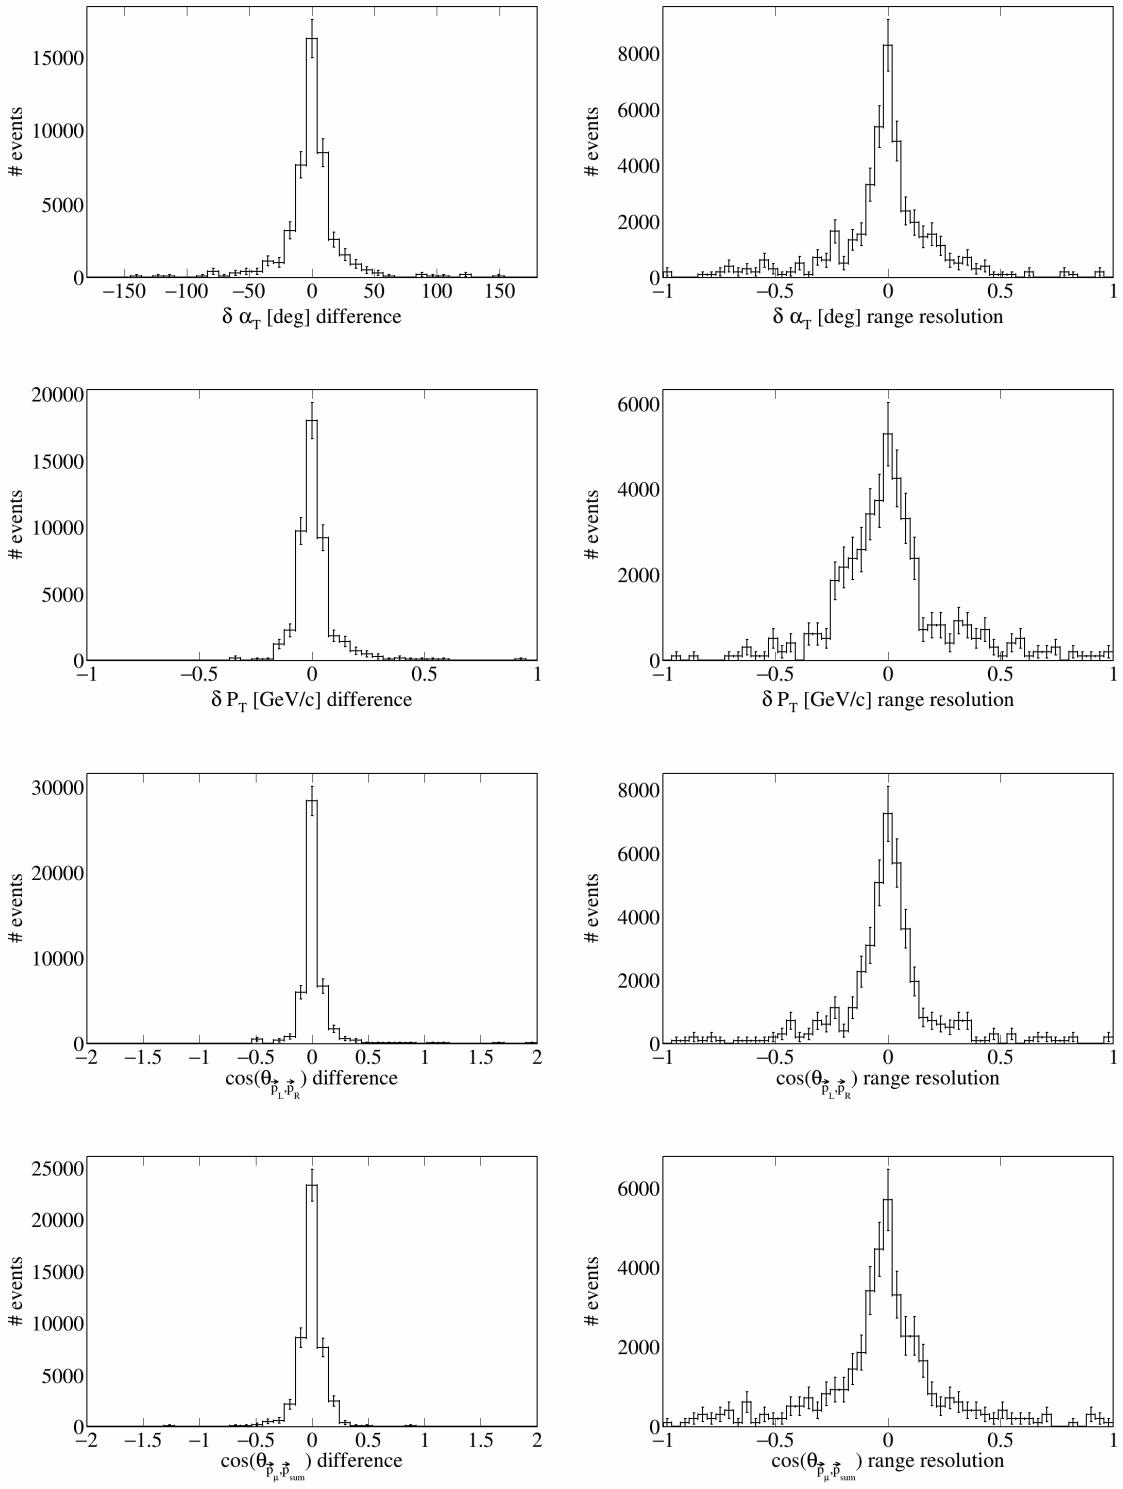

Figure 64: Difference and resolution plots for transverse and opening angle variables.

258 4 Cross-section results

259 We present the unfolded cross-sections obtained using the Wiener-SVD filter, and overlay it with the generators studied in the earlier sections of this document. The generator cross-sections are smeared using the
 260 additional smearing matrices, and the uncertainties are obtained using the unfolded total covariance matrix.
 261 The unfolded cross-sections are shown in Figures 65 to 67. Note that the “data points” shown are unfolded
 262 cross-sections of Monte-Carlo data from the SBND production, first results on real data are presented in the
 263 next section.
 264

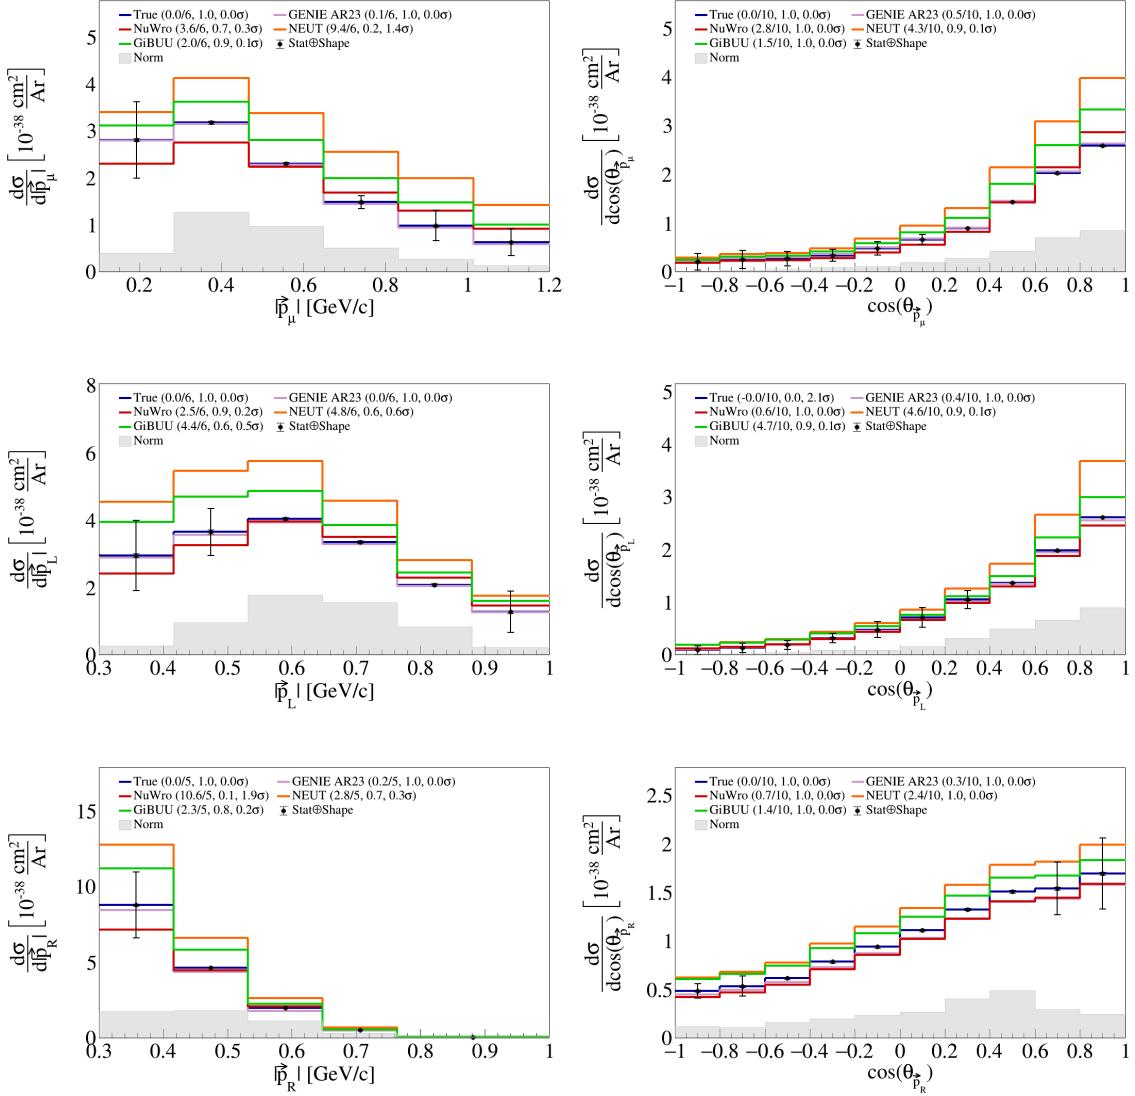

Figure 65: Cross-section results for momenta and opening angles of individual particles.

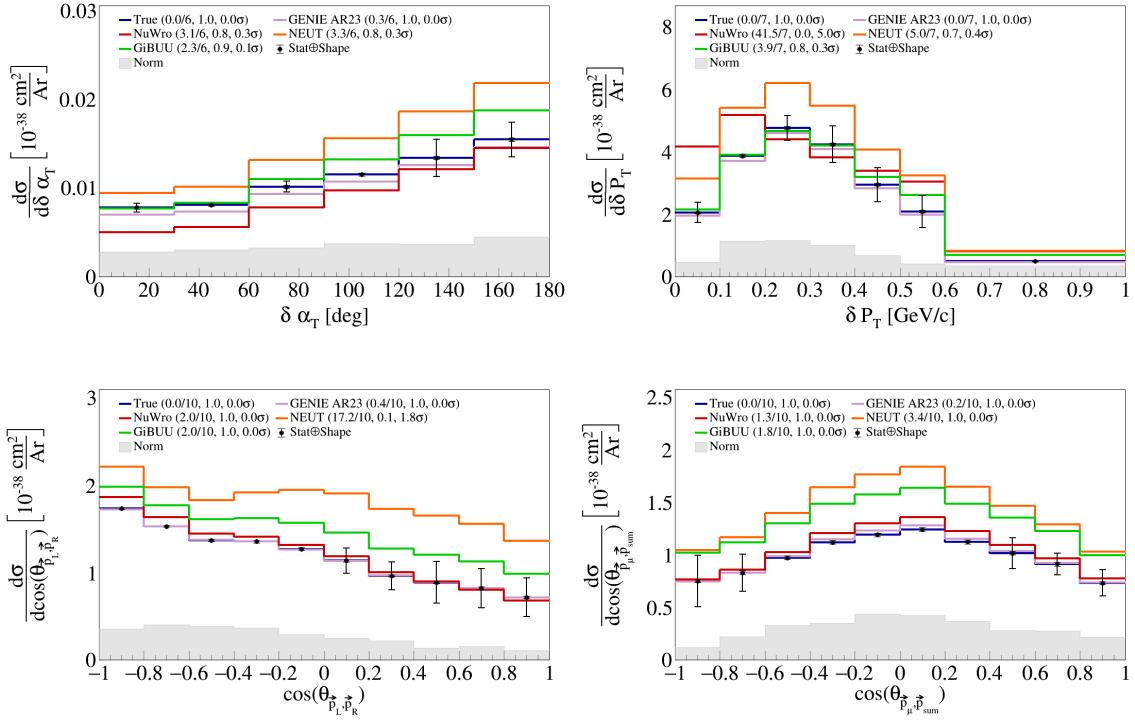

Figure 66: Cross-section results for transverse and opening angle variables.

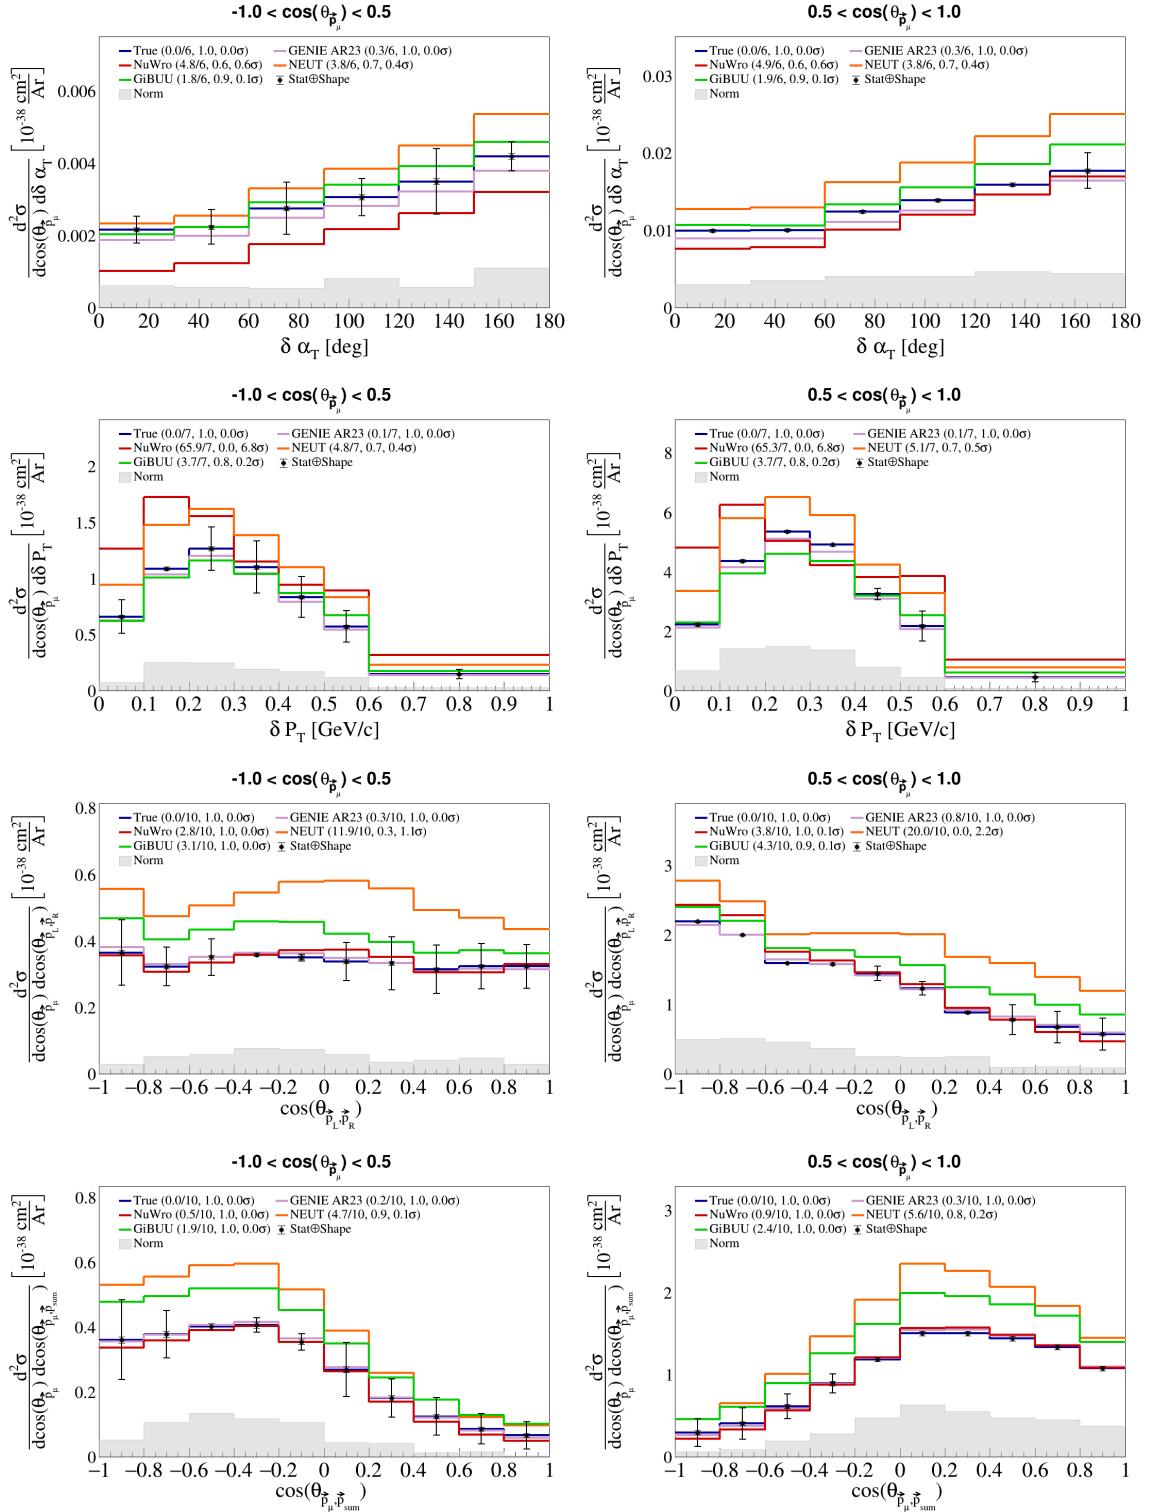

Figure 67: Cross-section results for sliced double differential variables.

265 **4.1 Cross-section uncertainties**

266 Figure 68 shows the single bin uncertainty breakdown using the cross sections. We used the unfolded
267 covariances obtained with the Wiener-SVD filter for each of the sources of uncertainty. The square root of the
268 corresponding fractional covariance matrix is normalized to the CV cross-section value for the uncertainties
269 to be obtained. The bin by bin cross section uncertainties for all our variables are shown in Figures 69 to 71.

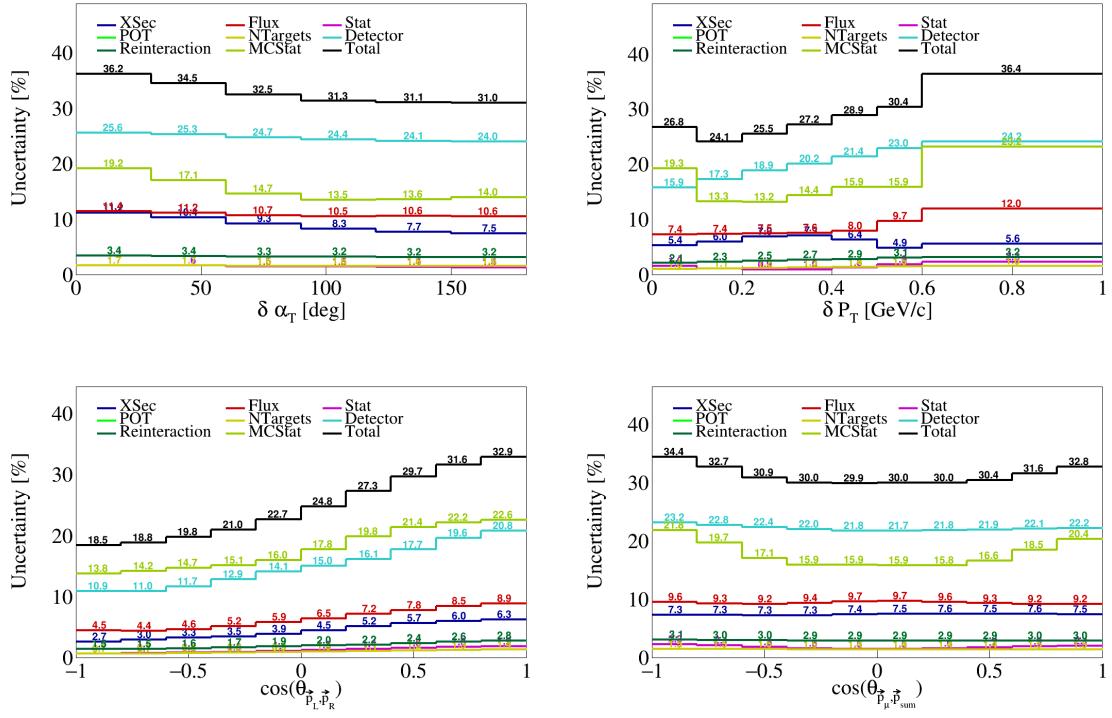

Figure 70: Bin by bin cross-section uncertainties for transverse and opening angles variables.

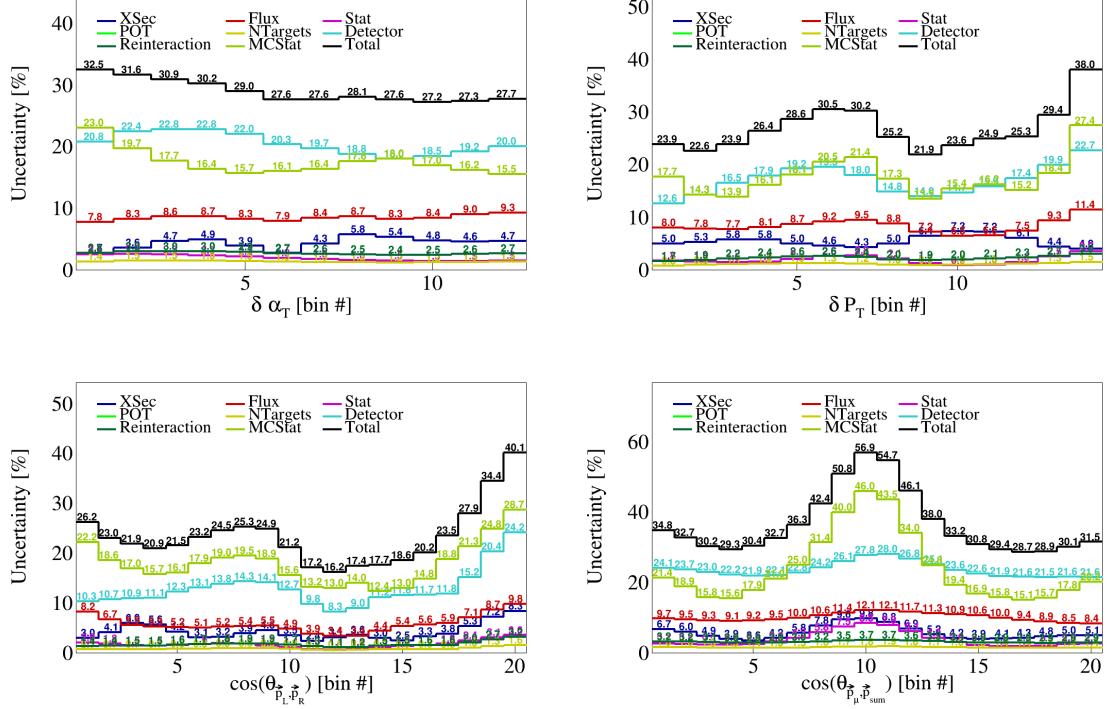

Figure 71: Bin by bin cross-section uncertainties for double differential variables.

270 **5 Fake data studies**

271 To test our unfolding procedure, we generate fake data by increasing the weight of certain events in our
272 Monte Carlo simulations. We give meson exchange current (MEC) events a weight of 2 in Section 5.1, and
273 quasi-elastic (QE) events a weight of 0.5 combined with a MEC weight of 1.5 in Section 5.2. We then unfold
274 these fake data using the nominal Monte-Carlo predictions from the GENIE AR23 generator. Therefore, the
275 input to the Wiener-SVD unfolding are: the response matrix constructed with the nominal predictions, the
276 true nominal signal, the reconstructed signal from the fake data (this is the only input that changes), and
277 the total covariance matrix, which in this case was the statistical covariance matrix for the fake data added
278 to the MC statistical and cross-section covariance matrices obtained with the nominal predictions.

279 After unfolding the fake data, we compare the unfolded fake data to the smeared fake signal and the
280 smeared nominal signal, using the additional smearing matrix obtained from the Wiener-SVD unfolding. We
281 then perform a χ^2 test to see if the unfolded fake data agrees with the smeared fake signal. Additionally, we
282 also report the p - and σ -values for the distributions. We expect to see good agreement between the smeared
283 fake signal and the unfolded fake data, while the smeared nominal signal should not agree with the unfolded
284 fake data. In other words, we expect below 1σ agreement between the smeared fake signal and unfolded fake
285 data.

286 **5.1 MEC 2x weight**

287 In this first fake data study, we give MEC events a weight of 2, while keeping all other events with a weight
288 of 1. We see that we are under 1σ agreement between the smeared fake signal and the unfolded fake data
289 for all our variables, while on or above 2.9σ with the smeared nominal signal, as expected. Therefore, we
290 can conclude that this fake data study was successful. The unfolded fake data along with the two smeared
291 signals is shown in Figures 72 to 75.

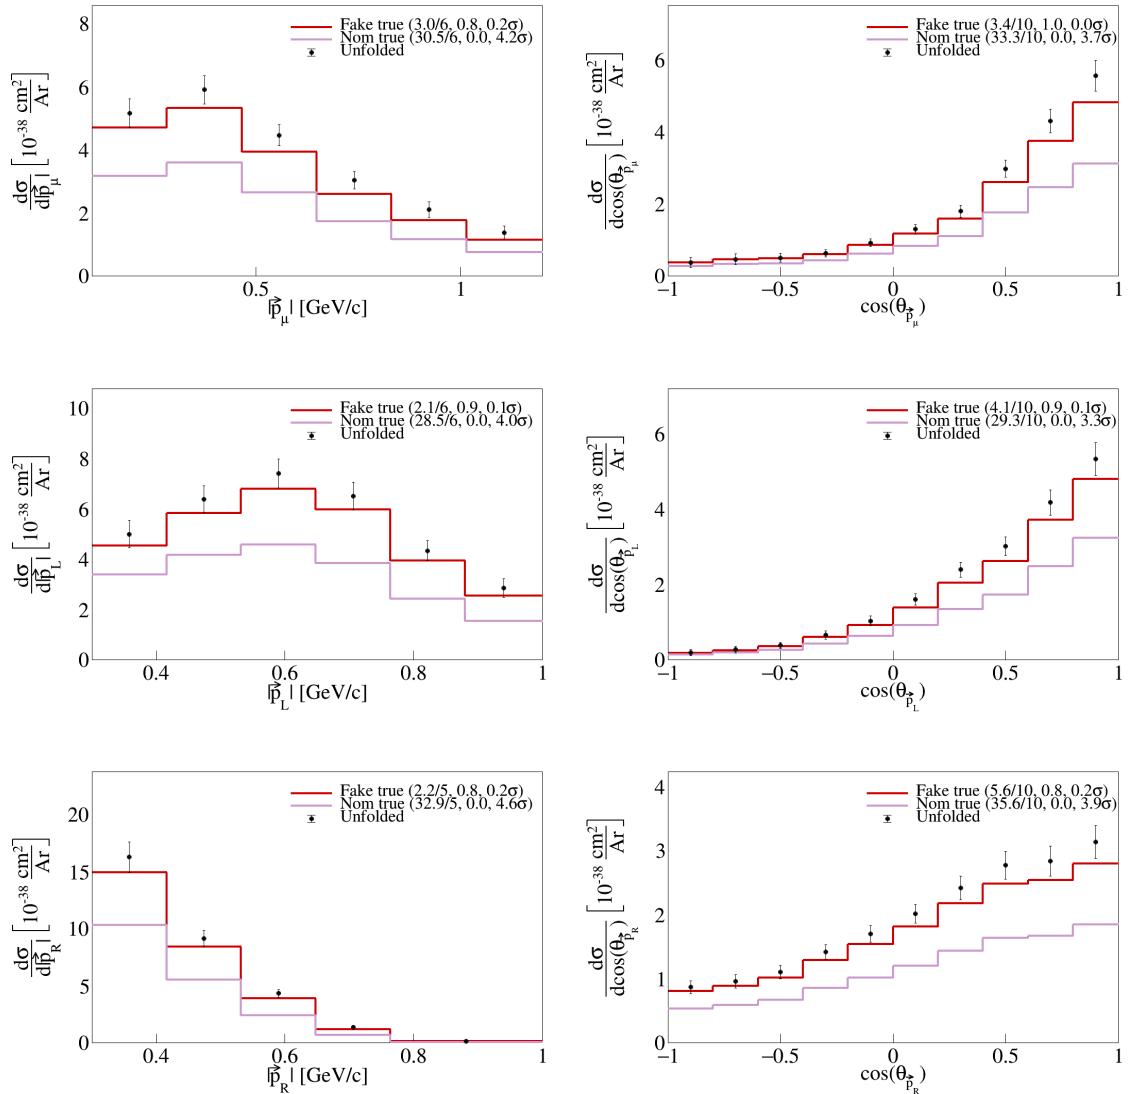

Figure 72: Unfolded 2x MEC fake data showing agreement with smeared fake signal data for single differential vector directions and magnitudes.

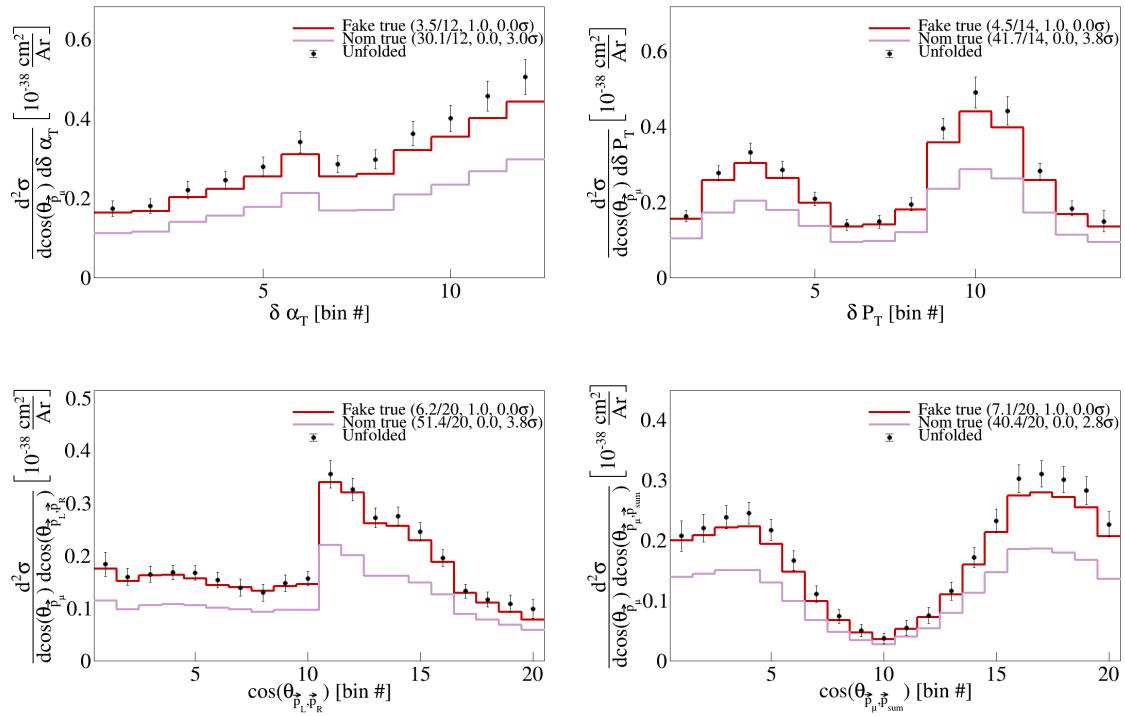

Figure 74: Unfolded 2x MEC fake data showing agreement with smeared fake signal data for serial double differential variables.

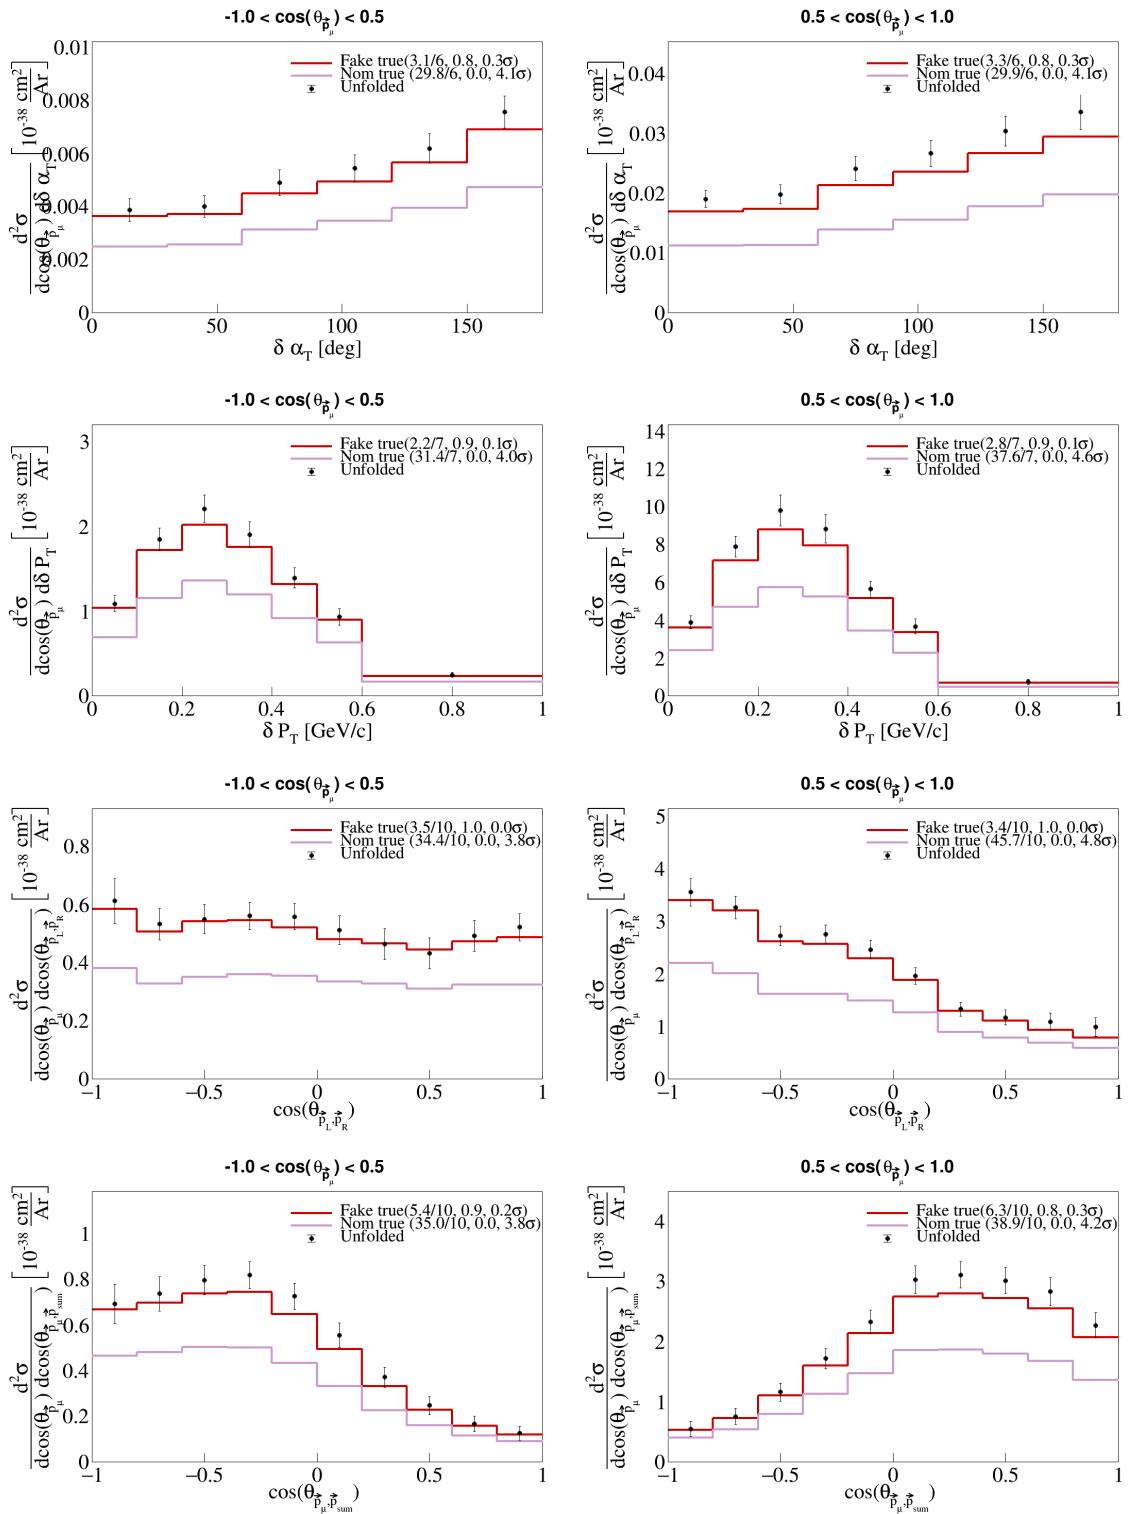

Figure 75: Unfolded 2x MEC fake data showing agreement with smeared fake signal data for sliced double differential variables.

292 **5.2 QE 0.5x and MEC 1.5x weights**

293 For this fake data study we give QE events a weight of 0.5 and MEC events a weight of 1.5, while keeping
294 all other events with a weight of 1. We see that we are under 1σ agreement between the smeared fake signal
295 and the unfolded fake data for all our variables, but contrary to the first study, we also see agreement with
296 the smeared nominal signal in many of our variables. The unfolded fake data for this study along with the
297 two smeared signals is shown in Figures 76 to 79.

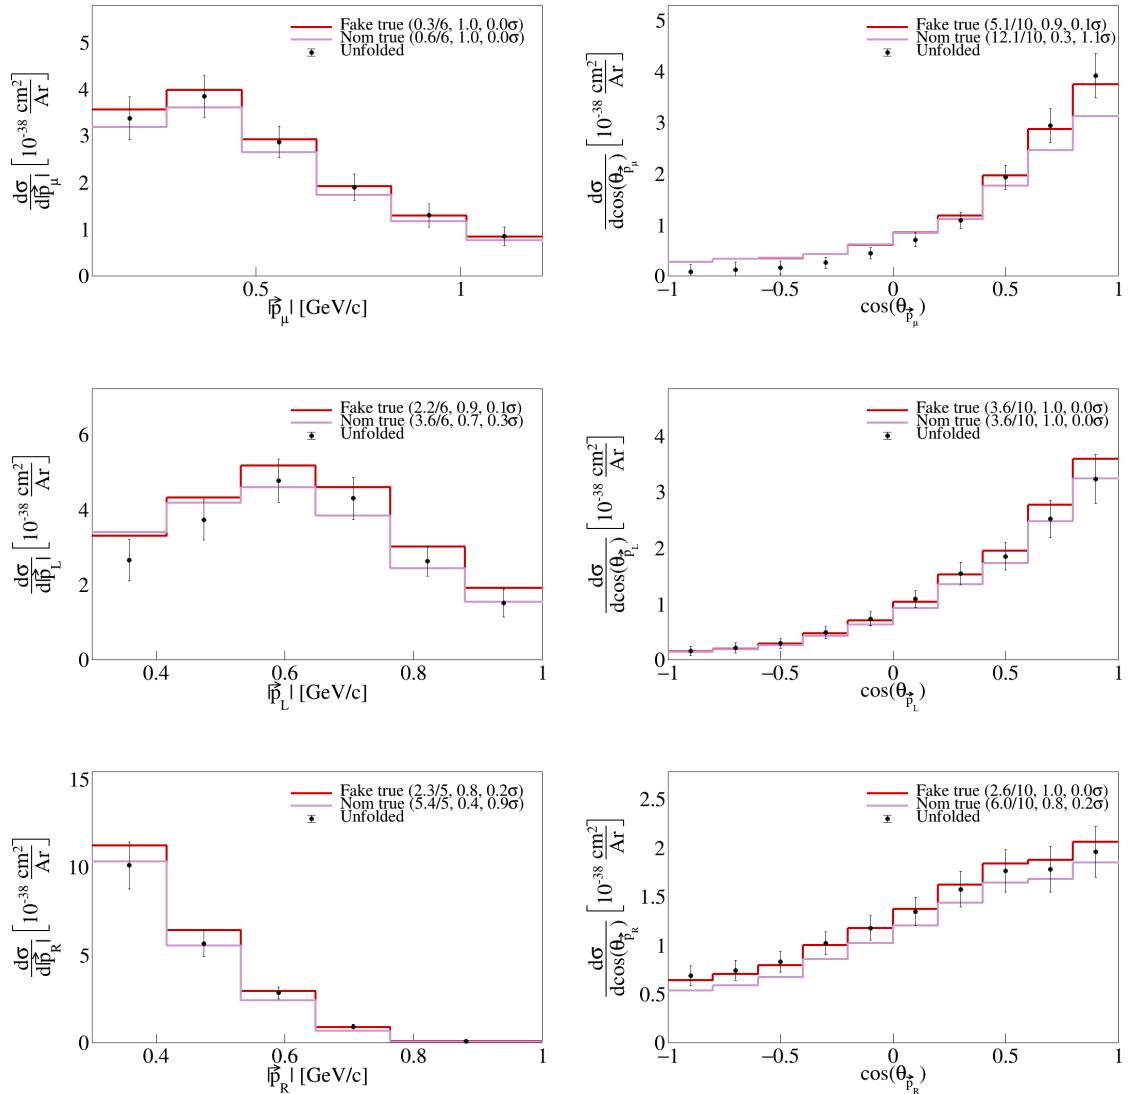

Figure 76: Unfolded combined weights fake data showing agreement with smeared fake signal data for single differential vector directions and magnitudes.

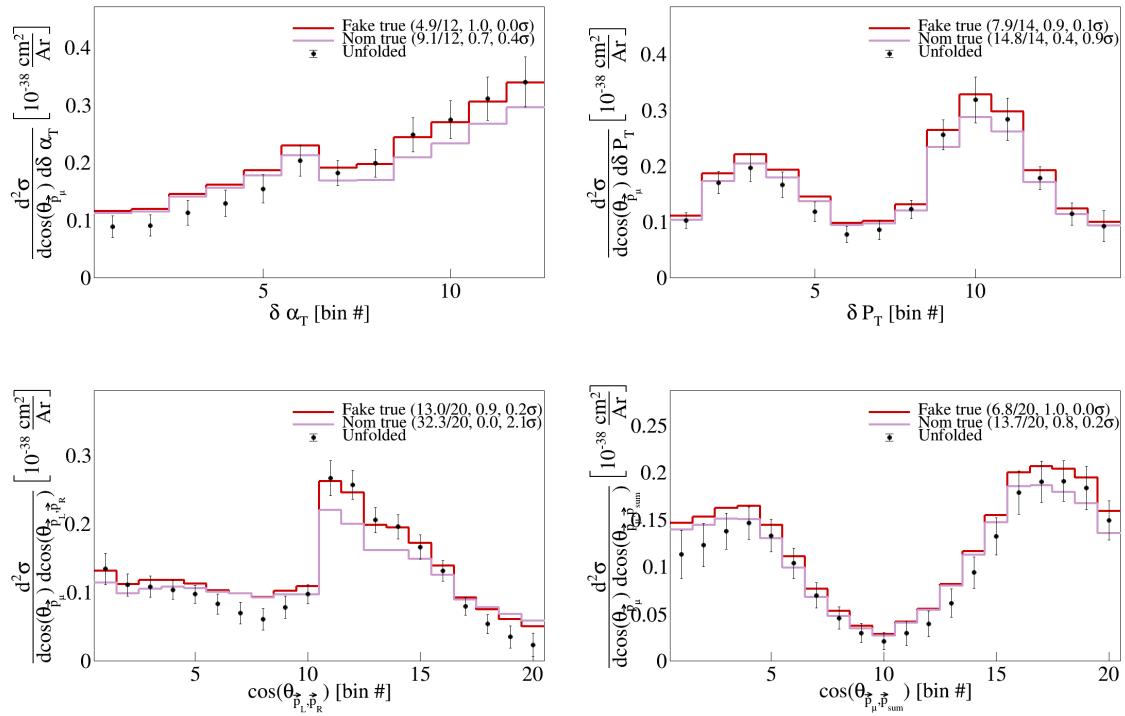

Figure 78: Unfolded combined weights fake data showing agreement with smeared fake signal data for serial double differential variables.

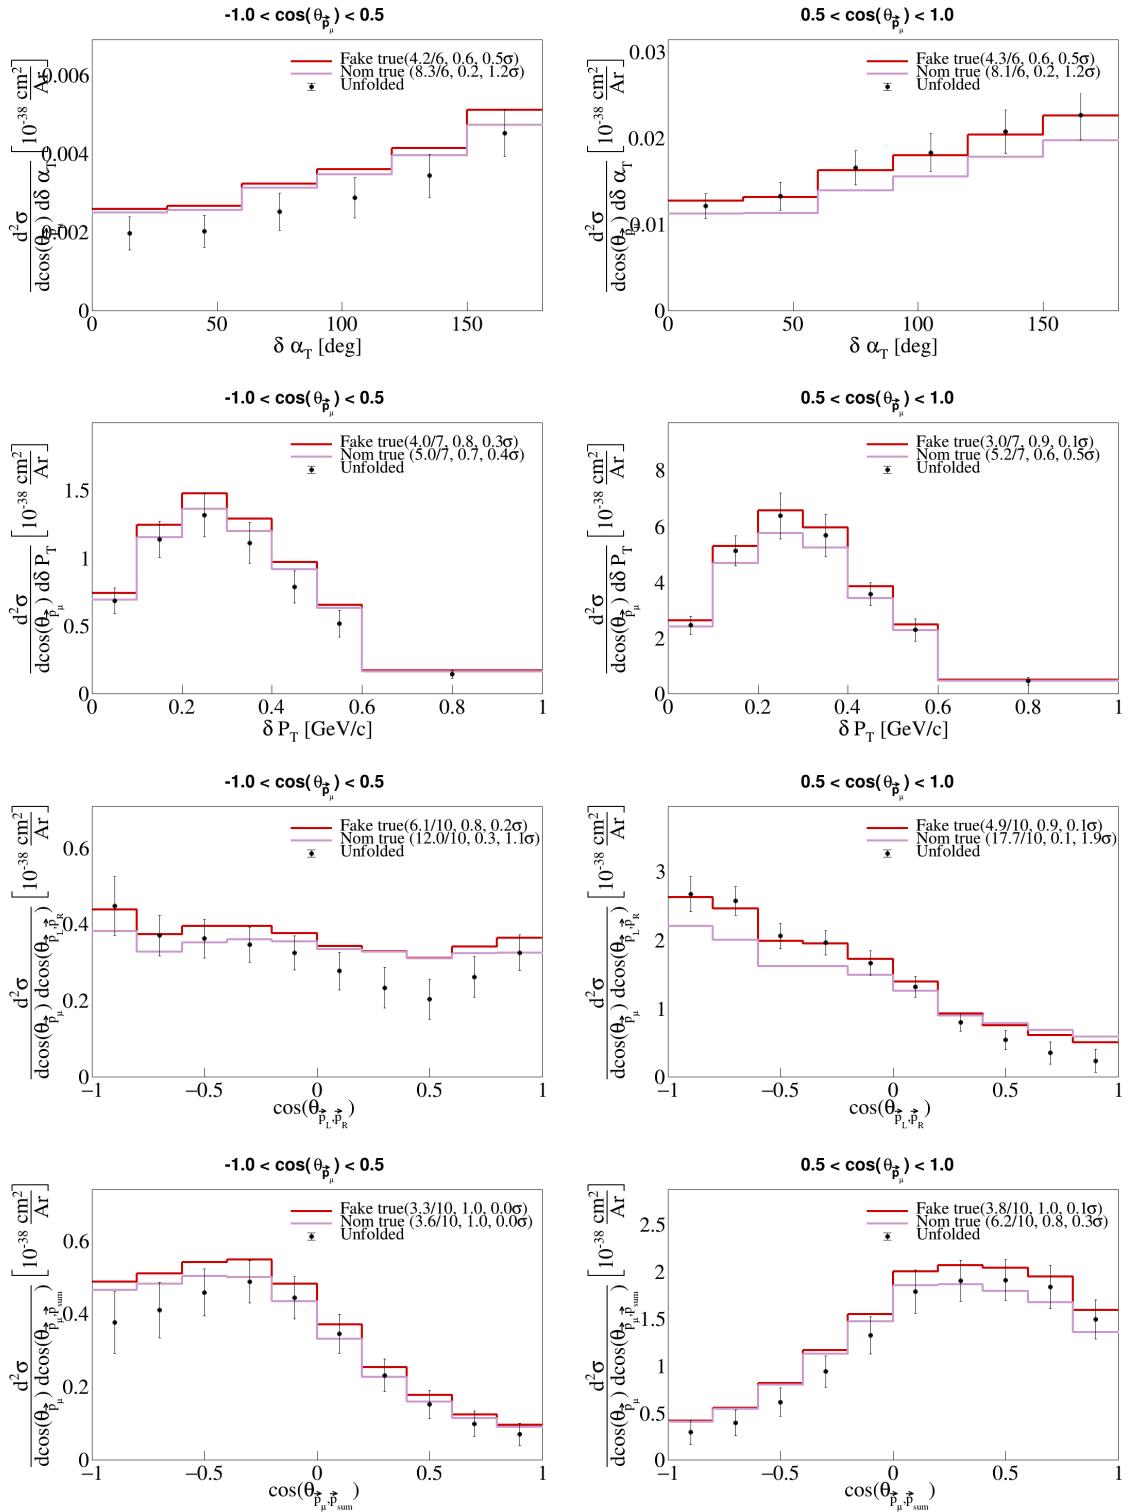

Figure 79: Unfolded combined weights fake data showing agreement with smeared fake signal data for sliced double differential variables.

298 6 SBND Data

299 Using the first available real data, we can perform initial comparisons between data and predictions. Since
 300 this first data does not have POT information yet, we only perform shape comparisons, i.e., we divide the
 301 event counts by the total number of events in the data. Further, the data does not have flash matching data
 302 necessary for our signal cuts. Therefore, we present some data before any cuts are applied (in neither the
 303 data nor the predictions), in Figure 80, which shows good agreement.

304 We show our usual variables in Figures 81 to 83, but these do not show the same agreement since we can
 305 not apply all the signal cuts, and the data is still low-statistics for signal events.

310 7.2 Flux systematics

311 In this appendix, the variations, covariance matrices, fractional covariance matrices, and correlation matrices
 312 are plotted for all of the flux systematics and variables.

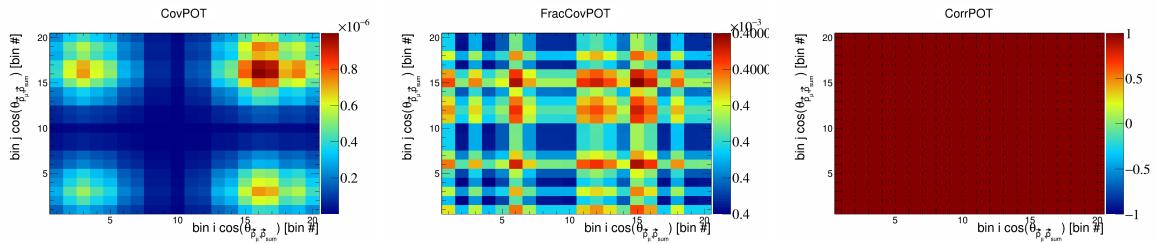

Figure 825: POT variations for $\cos(\theta_{\vec{p}_\mu, \vec{p}_{\text{sum}}})$ in $\cos(\theta_{\vec{p}_\mu})$.

319 7.5 Number of targets

320 In this appendix, the covariance, fractional covariance, and correlation matrices for the number of targets
 321 systematics are plotted.

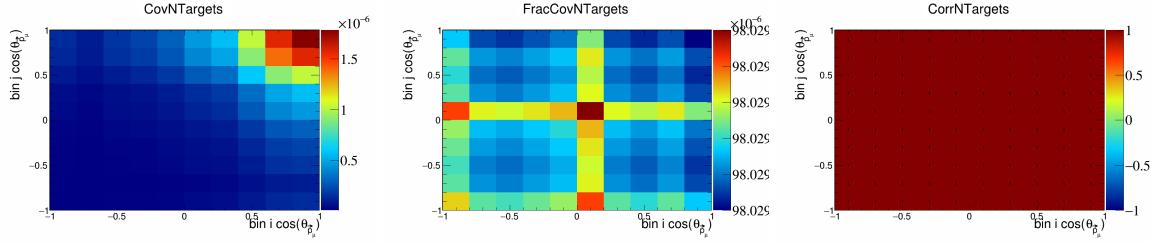

Figure 826: NTTargets variations for $\cos(\theta_{\vec{p}_\mu})$.

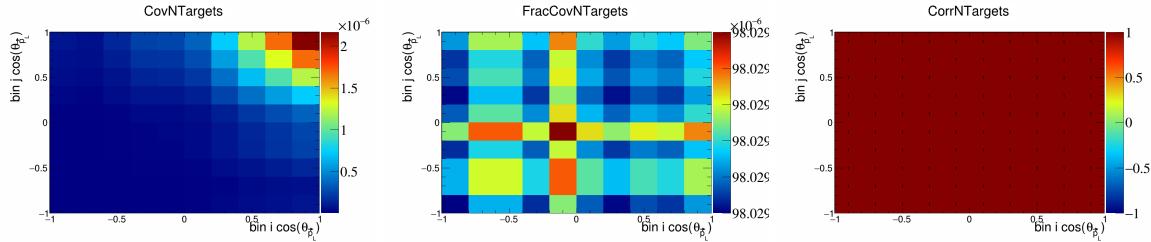

Figure 827: NTTargets variations for $\cos(\theta_{\vec{p}_L})$.

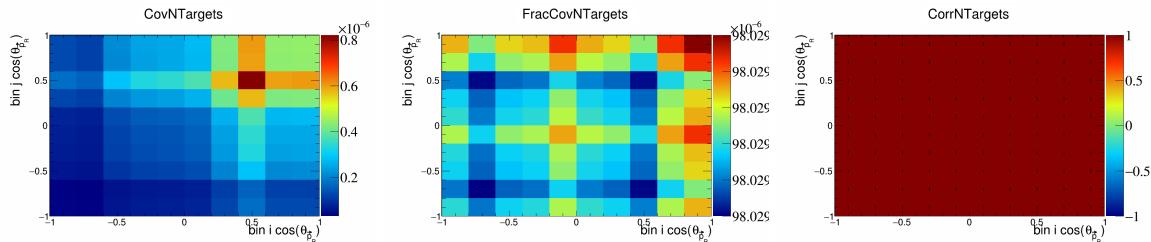

Figure 828: NTTargets variations for $\cos(\theta_{\vec{p}_R})$.
